

CONFIDENCE, SELF-SELECTION AND BIAS IN THE AGGREGATE^{*}

Abstract

The influence of behavioral biases on aggregate outcomes depends in part on self-selection: whether rational people opt more strongly into aggregate interactions than biased individuals. In betting market, auction and committee experiments, we document that some errors are strongly reduced through self-selection, while others are not affected at all or even amplified. A large part of this variation is explained by differences in the relationship between confidence and performance. In some tasks, they are positively correlated, such that self-selection attenuates errors. In other tasks, rational and biased people are equally confident, such that self-selection has no effects on aggregate quantities.

Keywords: Confidence, self-selection, biases, social institutions, markets

1 Introduction

Decades of experimental research on judgment and decision-making have revealed that people are subject to a wide variety of cognitive and behavioral biases. Yet, much of economics is concerned not with the quality of *individual* decisions but rather with the aggregate outcomes produced by *multiple* individuals interacting in institutions such as markets and organizations. The relevance of decision errors observed in the lab to economics therefore hinges to a great degree on whether these errors influence prices, distort allocative efficiency or have redistributive effects. While prior research has studied a host of classical reasons for why individual errors may not influence markets and organizations (such as wealth dynamics, arbitrage and learning from experience), we explore the idea that the psychological forces studied in behavioral economics might also affect how strongly individual errors influence economic outcomes. Specifically, we experimentally study to what degree decision makers' own beliefs about the quality of their decisions influences how strongly biases survive in economic aggregates.

Our point of departure is the observation that, in laboratory experiments, researchers “force” subjects to make cognitively difficult decisions, while real-world interactions often afford decision makers the freedom to self-select into or out of decisions. For instance, people might shy away from betting in markets when they fear that their judgments are fallible; they might be reluctant to aggressively bid in auctions over property rights for objects that they think they do not fully understand; or they might refrain from contributing their opinion to decision-making processes in groups and organizations when they suspect that they don't understand the matter at hand. Thus, self-selection might severely filter individual-level irrationalities, relative to the unfiltered measures we observe in the lab.¹

Our research is built on the observation that the above argument relies on the assumption that *selection is positive*, meaning that more rational people self-select more strongly into decisions that affect aggregate quantities. Yet, to date, we know relatively little about people's selection decisions across the multitude of cognitive biases studied by behavioral economists. A first-order statistic that may determine the economic effects of self-selection is the *confidence-performance correlation* of a cognitive error: the correlation between objective performance and confidence in the population. Using a simple model, we illustrate that if the error-prone are relatively less confident in the optimality of their decisions, then aggregate interactions (in, e.g., markets or organizations) will tend to effectively filter a bias. If, on the other hand, performance and confidence are unrelated, or even negatively correlated, then self-selection will not filter a bias, or

¹Gary Becker once opined in an interview that division of labor and resulting self-selection “strongly attenuates if not eliminates” effects of bounded rationality on economic aggregates (Stewart, 2005).

might even amplify its effect. Our simple model clarifies that what should matter for the economic effects of self-selection is not so much average overconfidence (i.e., overestimation, overplacement or overprecision in the taxonomy of Moore and Healy (2008)) but instead the correlation between performance and confidence. For example, as long as performance and confidence are positively correlated, self-selection will attenuate errors even in the extreme scenario that every single decision maker is overconfident.

As we discuss in detail below, a large literature in economics and psychology has studied to what degree various types of overconfidence vary across different types of tasks. By contrast, there is relatively little evidence on how the correlation between confidence and performance – which is the relevant object for studying and predicting the effects of self-selection – varies across cognitive biases. This gap in our knowledge appears crucial because there is immense diversity in the types of cognitive biases documented in the literature, in terms of both their domains (information-processing, financial decision-making, strategic sophistication etc.) and their underlying psychology (complexity, misleading intuitions, inattention etc.). Given this diversity, it is conceivable that the confidence-performance correlation varies markedly across types of errors.

We implement a series of pre-registered experiments to study the nature of self-selection under social institutions, and how this relates to the distribution of confidence. The main features of our experiment are (i) a broad set of 15 classical cognitive tasks and associated biases; (ii) three different self-selective “social institutions” in which subjects interact to produce aggregate outcomes; and (iii) direct measurements of across-subject confidence-performance correlations in each cognitive task. In total, our experimental data comprise almost 70,000 decisions obtained from 2,153 participants from a diverse online sample as well as expert forecasts from researchers in the field.

We consider 15 cognitive tasks, culled from the literatures on errors in statistical reasoning and logic, financial decision-making, and behavioral game theory. Examples include the winner’s curse, base rate neglect, correlation neglect, equilibrium reasoning, portfolio choice and thinking at the margin. Each task consists of two parts. In Part 1, subjects attempt to solve the cognitive task. In Part 2, we group subjects into ten-subject cohorts to participate in one of three maximally simple canonical social institutions.

In a *Betting* treatment, ten subjects participate in a parimutuel betting market, in which they bet on the optimality of their Part 1 decisions. In an *Auction* treatment, we assign subjects instead to an auction for the right to be paid a bonus based on the quality of their Part 1 decision. In a *Committee* treatment, we have all ten subjects decide how intensively to vote for their own Part 1 decision to influence a common group decision. In each of these institutions, subjects make a single decision that determines their degree of self-selection. By betting, bidding or voting less intensively, subjects can partly or fully select out of influencing institutional outcomes in a continuous way. We built

our design around three distinct social institutions not to intensively compare them but rather to ensure that our conclusions on self-selection across biases aren't overfit to any one idiosyncratic institutional setting. Indeed, we deliberately implemented maximally simple and static versions of these institutions, in order to be able to study an unusually large number of biases – a design choice that we believe can be profitably relaxed in future work.

In each of these institutions, the difference between how intensively cognitively biased versus unbiased subjects bid, bet or vote determines the aggregate outcomes institutions produce: the degree of bias in market prices in the betting market; the rate of bias among the winners in the auction; and the aggregate vote share for the optimal decision in the committee. By comparing these aggregate outcomes to average rates of bias (measured in Part 1), we can measure to what degree institutions “filter” biases – whether and by how much self-selection makes aggregate outcomes *appear* more rational than the raw rate of bias in the population would suggest.²

We find that, on average across all tasks, subjects who make optimal Part 1 decisions act more intensively in the Part 2 institutions. As a result of this positive selection, on average, biases are filtered in all three institutions, producing institutional aggregates that are less biased than subjects are. Importantly, however, we identify strong heterogeneity across biases in the degree to which this institutional filtering occurs. Some biases (e.g., iterated reasoning and exponential growth bias) are dramatically improved under all three institutions, while others (e.g., base-rate neglect and correlation neglect) are barely affected by self-selection. Some biases, such as the winner's curse, are even made more severe due to negative selection.

The heterogeneity in institutional filtering across cognitive tasks is very similar across the three different institutions. Although levels of improvement vary across institutions, it is almost always true that those errors that get filtered more effectively in one institution also get filtered more in the other institutions. The uniformity in *which* cognitive biases are most susceptible to improvement by self-selection suggests that the across-task variation is likely rooted in characteristics of the biases themselves.

Our motivating hypothesis (pre-registered prior to the experiment) is that this variation can be partly explained by a specific summary statistic of the distribution of confidence. As derived in a simple framework, our key prediction is that institutional filtering by self-selection critically depends on the cross-subject correlation between performance and confidence. To test this hypothesis, we measure the subjective percentage likelihood subjects assign to the proposition that they made a payoff-maximizing Part 1 decision, separately for each task. This allows us to ask a question of independent interest that

²As discussed in the Conclusion, we only focus on how self-selection affects the rationality / efficiency of the aggregate quantity that an institution produces, rather than on how it affects aggregate welfare.

has received little attention in behavioral economics so far: how strongly are confidence and performance correlated for different biases commonly studied in economics?

We find strong heterogeneity in the size and sign of the confidence-performance correlation across tasks. Although subjects are almost uniformly overconfident across all cognitive tasks, the correlations between confidence and optimality range from -0.13 (for misunderstanding mean reversion) to 0.39 (for gambler’s fallacy).

As predicted by our simple framework, this correlation is strongly predictive of institutional filtering across cognitive tasks ($r \approx 0.76$ – 0.91). In tasks in which the confidence-performance correlation is strongly positive, self-selection in social institutions effectively filters errors. These results suggest that in order to understand and predict to what degree cognitive errors will be “filtered out” of aggregate quantities through self-selection, we must understand the precise distribution of confidence, rather than the average level of overconfidence in the population.

Given the moderate number of cognitive tasks in our study (15), it is difficult to draw definitive conclusions about which task characteristics lead to better confidence-performance correlations. Nonetheless, in an exploratory analysis, we use the “peakedness” of the distribution of answers to classify tasks according to whether cognitive errors reflect strong misleading intuitions or a high degree of complexity. We identify some tentative evidence that cognitive tasks that evoke strong intuitions (such as correlation neglect) are associated with lower confidence-performance correlations than tasks that do not evoke a strong gut feeling (such as backwards induction).

The importance of directly measuring the performance-confidence correlation is reinforced by the observation that it is non-trivial for economists to forecast the magnitude of institutional filtering or the size of the confidence-performance correlation *ex ante*. To underscore this point, we ran a survey asking a panel of experts to guess, for a variety of cognitive tasks, (i) to what degree performance and confidence go hand-in-hand; and (ii) to which degree one of our institutions (auctions) filters errors. We find that while the experts are not far off, they consistently overestimate both the degree of institutional filtering and the confidence-performance correlation. Moreover, the experts underpredict variation across cognitive tasks.

In all, we view our paper as making three contributions. (i) Our results provide direct evidence on which types of cognitive errors get filtered out through self-selection. (ii) We document that understanding or predicting institutional filtering of a given cognitive bias requires that we take into account the confidence-performance correlation in the population (rather than, e.g., the frequency of errors or the average level of overconfidence). This is especially valuable from a methodological perspective because it suggests a simple blueprint: researchers who study cognitive biases can gauge the likely strength of institutional filtering for these biases without actually implementing laboratory insti-

tutions, by appending a simple confidence question to their experiment and calculating the confidence-performance correlation. (iii) We contribute some of the first systematic evidence on the confidence-performance correlation across a large set of widely studied behavioral economics biases.

Our paper ties into several literatures. First, our work relates to an ongoing discussion about when behavioral anomalies affect aggregate quantities (e.g., Russell and Thaler, 1985; List, 2003; Barberis and Thaler, 2003; Fehr and Tyran, 2005; Sonnemann et al., 2013). Various experimental contributions have studied the effect of social institutions such as markets and groups on several biases and economic behaviors (e.g., Camerer, 1987; Friedman, 2010; Charness and Sutter, 2012).³

Second, our paper relates to work on self-selection. Most closely related is the literature on excess entry (Camerer and Lovo, 1999; Cain et al., 2015; Hollard and Perez, 2021), which studies the link between individual confidence and market (or game) entry.⁴ Our main contribution to this line of work is to study the effectiveness of social institutions more systematically for a broad set of cognitive tasks, and to show that the performance-confidence correlation is an effective way to conceptualize and empirically predict how and why institutional effects differ strongly across cognitive biases.

Third, our work relates to the literature on how different aspects of confidence and self-awareness vary across cognitive tasks (Moore and Healy, 2008). While we highlight and measure the confidence-performance correlation, various earlier literatures have studied how types of average overconfidence vary across tasks, such as in the hard-easy effect (e.g., Koriat et al., 1980; Erev et al., 1994; Moore and Cain, 2007).⁵ A prominent example of this body of research is work in psychology on the so-called “bias blind spot”: the tendency for people to believe they are less susceptible to behavioral biases than other people are (e.g., Scopelliti et al., 2015; Pronin et al., 2004, 2002; Pronin, 2007). A typical paradigm in this literature asks subjects to self-report on a qualitative scale whether they or others are more likely to fall prey to some bias that is described to them verbally. These papers document that there is substantial variation in average overplacement (“relative overconfidence”) across tasks. A main difference between our work and this line of research is that we study (and argue for the importance of) the confidence-performance correlation. Indeed, a key conceptual point that emerges from our theoretical and empirical analysis is that the average degree of overconfidence or overplacement (the focus of virtually all of this literature) is largely irrelevant for under-

³While we study self-selection (voluntary choice to remove oneself from, e.g., markets), Kendall and Oprea (2018) study the “market selection hypothesis,” which asks whether markets reduce biases because error-prone people eventually run out of investment funds.

⁴Odean (1999, 1998) studies the distribution of overconfidence across investor types and its implications for overtrading and other market anomalies.

⁵Loosely related is also work on (lack of) awareness of present bias (O’Donoghue and Rabin, 1999) and its implications for market outcomes and welfare (e.g., Carrera et al., 2022; John, 2020).

standing whether self-selection into institutions attenuates cognitive biases.

Most closely related to our paper is, work that, like us, directly examines the confidence-performance correlation, which is variably referred to as “relative accuracy,” “monitoring resolution” or “discrimination” in the psychology literature (e.g., Yaniv et al., 1991; Nelson, 1984).⁶ Psychological experiments show a link between the confidence-performance correlation and the effectiveness of groups in aggregating individual knowledge (e.g., Snizek and Van Swol, 2001; Silver et al., 2021, see also the overview in Online Appendix Table 3). The main differences relative to our work are that (i) this literature studies knowledge questions (“wisdom of crowd” effects) rather than cognitive biases as we do here, and (ii) it does not study the formal institutions of interest to economists like markets.

The paper proceeds as follows. Section 2 lays out our experimental design and Section 3 derives our predictions. Section 4 presents results on institutional improvements across tasks and Section 5 examines the role of the confidence-performance correlation. Section 6 reports on our expert survey. Section 7 concludes.

2 Experimental Design

2.1 Overview

Our goal is to design an experiment to answer three questions. First, to what degree does self-selection in basic economic institutions filter out the effects of different cognitive biases? Second, how does the confidence-performance correlation vary across biases that are commonly studied by behavioral and experimental economists? And third, how strongly is the institutional filtering of different biases predicted by variation in this confidence-performance correlation?

Our experiment consists of 15 periods, each consisting of two parts:

- **Part 1: Cognitive Task:** The subject makes a decision in one of 15 distinct cognitive tasks, randomly ordered across the 15 periods. The tasks all correspond to widely-studied cognitive biases in behavioral economics.
- **Part 2: Institutional Choice:** The subject participates in an anonymous social institution that involves a ten-person cohort: *Betting* markets, *Auctions* for decision rights, or *Committee* voting. She then makes an “institutional choice” linked to her Part 1 decision: a bet on the optimality of her Part 1 decision; a bid on the right to earn a bonus if her Part 1 decision was optimal; or a vote for her Part 1 decision to

⁶Much of this work originates from earlier theoretical work that decomposed the quality of forecasts into components that include the confidence-performance correlation (Yates, 1982; Murphy, 1973).

be adopted by her cohort. Her earnings for Part 2 depend on (i) the optimality of her Part 1 decision, (ii) her institutional choice and (iii) the institutional choices of others, in a manner that differs across institutions.

In some treatments, subjects are not assigned to an institution in Part 2 but are instead simply asked to state their confidence (in percentage terms) that they made an optimal decision in Part 1.

The timeline is as follows: subjects (i) read computerized instructions; (ii) are required to pass a comprehension check; (iii) provide a response in the first cognitive task; (iv) indicate confidence or make a decision in a social institution related to the first task (depending on treatment); (v) repeat (iii) and (iv) for the second task etc.

2.2 Part 1: Cognitive Tasks

We selected 15 cognitive tasks based on four principles. First, we wanted tasks with associated biases that reflect a range of well-known and widely-studied errors from behavioral and experimental economics. Second, we desired to sample tasks that relate to a variety of “Econ 101” principles of rationality and, hence, capture distinct forms of economically-relevant reasoning. Third, we focused on tasks associated with cognitive rather than motivational biases such as present bias. Fourth, we wanted tasks that have very short and simple instructions, allowing us to observe every subject under all 15 tasks. In practice, this means that we selected tasks from the literature and then partly simplified the instructions or the problem setup.

Our objective was not to select a set of tasks that is representative of the range of tasks we believe people encounter in everyday life. Instead, we deliberately sought out tasks that produce well-documented biases, i.e., on which a considerable fraction of people perform poorly. This approach is warranted here because our research question (how institutions filter biases) is predicated on the existence of biases in the first place. Nonetheless, we strove to select biases that are broadly representative of those studied in the *cognitive bias* literature.⁷

We summarize the tasks in Table 1 and provide more details in Online Appendix A. Task instructions are provided in Online Appendix F. We divide the table into several sections to highlight that our tasks represent a broad swath of the different violations of “Econ 101” rationality postulates that economists and psychologists have documented. These include widely discussed errors in information-processing and statistical reason-

⁷The confidence-performance correlation has been shown to depend on task features such as average performance (see, e.g., Koriat, 2012). Consequently, we caution against interpreting our findings across the set of 15 tasks as being representative for alternative sets of tasks.

ing; logic problems; errors in strategic reasoning (behavioral game theory); failure to identify constrained optima; and various errors related to financial decision-making.

A central distinction between our selection of tasks and previous work comparing collections of biases is that we deliberately avoided motivational, or preferences-related, behavioral regularities, which motivate the majority of tasks studied in Stango and Zinman (2020) and Chapman et al. (2018). We avoided preference-oriented anomalies because our research questions require tasks in which there is a clearly identifiable “right answer,” which is typically not available for preference anomalies. Like Stango and Zinman (2020), our set of tasks includes the gambler’s fallacy and exponential growth bias.

Our empirical measure of performance in each task is a binary indicator that codes whether a response is (exactly) optimal, i.e., expected payoff-maximizing. Clearly, the requirement that a response be exactly optimal is more demanding in some tasks than in others for a variety of reasons, and we discuss the corresponding considerations in Section 2.6.

2.3 Part 2: Social Institutions

2.3.1 Overview

Our goal in Part 2 is to understand to what degree common social institutions motivate people to self-select out of participation in that institution. Our goal is not to exhaustively cover every conceivable type of institution but, rather, to focus on a few maximally simple institutions that are widely studied by economists. First, we selected two canonical types of market institutions that each rely on a different classical idea about how markets can filter out biases:

- **Betting markets:** A classical idea in economics is that well-informed bidders in speculative markets will be incentivized to bet more aggressively than less well-informed bidders, producing prices that efficiently aggregate information by putting greater weight on higher quality information. In principle, this same mechanism can apply also to traders with cognitive biases: to whatever degree confidence and performance are correlated, less biased traders will have incentives to bid more aggressively than more biased traders, producing prices that reflect the beliefs of the former more than the latter.
- **Allocative markets:** A second classical idea in economics is that people who more highly value products, resources and factor inputs will bid more for them in markets, causing markets to direct these resources to their most highly valued use. In standard models (absent externalities), competitive prices do just this by efficiently allocating goods to the subset of market participants who express the highest value

Table 1: Overview of cognitive tasks and associated biases

Task	Bias / Description
Information Processing and Statistical Reasoning	
Base rate neglect (BRN)	Ignoring base rates when computing posteriors. ‡ Adaptation of taxi-cab problem from Tversky and Kahneman (1982).
Correlation neglect (CN)	Failing to account for non-independence of data in inference. ‡ Adaptation of tasks from Enke and Zimmermann (2019).
Balls-and-urns belief upd. (BU)	Failure to calculate Bayesian posterior. ‡ State probabilistic beliefs about which urn a colored ball is drawn from.
Gambler's fallacy (GF)	Failing to properly attribute independence to iid draws. ◦ Coin flipping task adapted from Dohmen et al. (2009).
Sample size neglect (SSN)	Failing to account for effect of sample size on precision of data. ◦ Adaptation of hospital problem from KT (1972); Bar-Hillel (1979).
Regression to mean (RM)	Failing to account for noise / failure to recognize regression to the mean. ◦ Adaptation of task from Kahneman and Tversky (1973).
Acquiring-a-company (AC)	Failing to properly condition on contingencies, à la the Winner's Curse. * Bidding task against computer as in Charness and Levin (2009).
Logic	
Wason task (WAS)	Failure to gather valuable evidence / positive hypothesis testing. ◦ Adaptation of 4-card task from Wason (1968).
Cognitive reflection test (CRT)	Following intuitive but misleading 'System 1' intuitions. ◦ Adaptation of Frederick (2005).
Strategic Reasoning	
Backw. ind. / iter. reason. (IR)	Limited depth of reasoning in recursive reasoning problems. * 1-player beauty contest game, à la Bosch-Rosa and Meissner (2020).
Equilibrium reason. (EQ)	Failure to forecast effects of incentives in dominance solvable games. ◦ Identify higher earning payoff matrix, adapted from Dal Bó et al. (2018).
Constrained Optimization	
Knapsack (KS)	Failure to identify optimal bundle in constrained optimization problem. * Knapsack problems taken from Murawski and Bossaerts (2016).
Financial Reasoning	
Thinking at the Margin (TM)	Thinking about average instead of marginal costs/benefits. * Adaptation of marginal tax task from Rees-Jones and Taubinsky (2020).
Portfolio choice (PC)	Failure to construct efficient portfolios due to 1/N heuristic. * Choose optimal portfolio vs. dominated 1/N portfolio.
Exponential growth bias (EGB)	Underestimate the exponential effects of compounding. † Interest rate forecasting problem adapted from Levy and Tasoff (2016).

Notes. Symbols indicate Part 1 payoff function in experimental currency units (ECUs). *: payoffs correspond to implied game payoffs as described in the task; ◦: 100 ECUs if optimal choice, nothing otherwise; †: 100-d and ‡: 100-3d where d = difference between response and expected payoff-maximizing / Bayesian response.

for goods in their bids. For example, if a resource is cognitively difficult to make efficient use of (i.e., to put it to its most productive use), then if the confidence-performance correlation is strongly positive, relatively unbiased agents will tend to place higher value on the resource and thus outbid their competitors, acquiring the resource and thereby protecting it from inefficient use by biased competitors.

To these market mechanisms, we add a generic institutional mechanism commonly used to make decisions inside organizations:

- **Committees:** Committees inside organizations aggregate opinions informally through discussion or formally through voting. Participants can often self-select out of this aggregation simply by not raising their voice in discussion, not adding their judgment to the proceedings or abstaining from voting. This self-selection could cause the committee’s aggregate decision to be less biased than its average member.

Notice that each of these three types of institutions are influenced by self-selection in distinct ways. In betting markets, agents are motivated to self-select out of the market (to bet less aggressively) by a desire to avoid private losses due to mistaken judgments. Potential institutional “filtering” occurs by improving the accuracy of the market price relative to the price that would have emerged if all agents had bet equally aggressively. In allocative markets, agents self-select out of the market by bidding less aggressively in order to avoid acquiring items that they believe they cannot effectively extract value from. Potential institutional filtering occurs by assigning resources to the least biased participants in the market rather than to bidders at random. Finally, in committees, agents are motivated to self-select out of the discussion by a fear that adding their judgments to the pool will worsen the group’s aggregate decision and thereby decrease their own payoff. Potential institutional filtering occurs by producing aggregate decisions that reflect the beliefs of only the most competent participants rather than the belief of the average member of the committee.

In reality, all of these institutions potentially filter cognitive biases through many “classical” mechanisms other than self-selection, including learning from feedback, arbitrage, experimentation and wealth dynamics. We do not intend to argue that these are unimportant. However, for the sake of simplicity of the experimental design, we here abstract away from all of them and focus on the self-selection mechanism.

2.3.2 Implementation and Institutional Details

For the experiment, we aimed to find the simplest possible version of these institutions: (i) implementations that are static and require only a single, simple decision from each participant and (ii) implementations in which the self-selection decision can be represented for subjects in a very similar fashion.

Betting Markets: Parimutuel Betting. We implemented a *parimutuel betting market* – a particularly simple betting institution. In it, bettors submit monetary bets on multiple securities, only one of which will turn out to be valuable. The total money bet is then redistributed to bettors on the winning security in proportion to the amount each of those

agents bet. A canonical example for parimutuel betting markets is horse-race betting. However, there are also direct analogies to financial markets, where betters bet on one of multiple mutually exclusive states of the world, such as whether an asset will increase or decrease in value. Indeed, parimutuel betting markets are frequently implemented in laboratory experiments because of their simplicity and appealing resemblance to real-world markets (e.g., Plott et al., 2003).

In our implementation, participants were informed that a cohort of 9 other subjects in the study completed exactly the same Part 1 cognitive task as they did and that the ten participants would be grouped together into a betting market on their answers to these questions. In each of these Part 2 markets, each participant is endowed with 100 points (ECUs). The subject's task is to decide how many of those 100 points (if any) to bet on the proposition that her own Part 1 response was optimal. This decision was implemented using a simple slider that ranged from 0 to 100, with no default value, see Online Appendix Figure 7 for an example screenshot.

The performance metric of interest in the betting market is the price of the security that is linked to the optimal Part 1 decision. Denoting the points bet by participant i as b_i and x_i as an indicator that equals 1 if the participant's Part 1 choice was optimal, the parimutuel price for this asset is given by:

$$\theta^{Betting} = \frac{\sum_{i=1}^{10} x_i b_i}{\sum_{i=1}^{10} b_i} \in [0, 1] \quad (1)$$

Notice that this price simply amounts to a re-weighting of individual Part 1 decisions, x_i , as a function of how many points each individual bets. For example, if all market participants bet the same amount (no self-selection occurs), then the market price will simply equal the raw optimality rate, $\bar{x}$, for the cohort. On the other hand, if only participants who make the optimal decision in Part 1 actually bet, the market price will equal one – the same price that would occur if all participants in the cohort were in fact unbiased. In our analyses, we can therefore easily gauge institutional filtering by comparing this price with the raw fraction of optimal Part 1 responses.

Individual payoffs are determined as follows. If a subject's Part 1 decision was not optimal, all points bet are lost and the subject only keeps the remaining endowment. If the subject's Part 1 decision was optimal, the subject's bonus is given by

$$\pi_i^{Betting} = \frac{b_i}{\theta^{Betting}} + (100 - b_i) \quad (2)$$

As a result, a subject is guaranteed to earn back at least what she bet (if their Part 1 decision was optimal), and the bonus is higher the more points are bet by subjects who

did not take the optimal Part 1 decision.

Allocative Markets: Discriminatory Auctions. For allocative markets, we implemented a sealed bid “discriminatory auction,” a natural extension of a first-price auction to a setting with multiple winners. Specifically, in a group of 10, each subject receives an endowment of 100 ECU and decides how many to bid using a slider, see Online Appendix Figure 9. The five highest bidders win the auction and pay their own bid.⁸ In exchange, the winners receive a bonus of 100 ECU if and only if their own Part 1 decision was optimal. Under standard assumptions, there is a symmetric and monotone equilibrium for discriminatory auctions that implements an efficient allocation to the M highest value bidders (Krishna, 2009, p.179). Intuitively, participants who believe that their Part 1 decision was incorrect have little incentive to bid.

The performance metric of interest in allocative markets is the optimality rate in the subset of participants who win the auction. Denoting the set of winners Ω :

$$\theta^{Auction} = \frac{\sum_{i \in \Omega} x_i}{5} \quad (3)$$

If no self-selection occurs (if everyone bids the same amount), resources will be assigned randomly and the expected performance will be $\bar{x}$, the raw optimality rate in the cohort. On the other hand, if five optimal participants submit the five highest bids, the performance metric will be one – the same value that would occur if *all* participants in the cohort were unbiased. In our analyses, we can, again, compare this outcome of the auction to the raw Part 1 optimality rates.

Committees: Utilitarian Voting. Once again, subjects were assigned to groups of 10. Each participant was endowed with 100 votes, any number of which a subject could submit for their own Part 1 decision (the remainder are unused). These votes can be interpreted either as literal votes or instead as the intensity with which a participant argues in favor of her Part 1 solution (e.g., the number of minutes she chooses to spend arguing in a group discussion). This decision was again represented using a simple slider, see Online Appendix Figure 8.

The institutional performance metric of interest is the fraction of votes placed on the optimal decision. Denoting by v_i subject i ’s number of votes:

$$\theta^{Committee} = \frac{\sum_{i=1}^{10} x_i v_i}{\sum_{i=1}^{10} v_i} \in [0, 1] \quad (4)$$

⁸If there are multiple fifth-highest bidders, the auction randomly selects from among the relevant set. The main reason we implemented a discriminatory auction with five winners rather than a single-unit auction with only one is that with five winners the performance of the institution can be more precisely estimated and doesn’t rely as much on random noise in who happens to be the highest bidder.

All subjects in a group made the same profit, $\pi_i^{Committee} = 100 \times \theta^{Committee}$. As a result, it doesn't matter for a subject's payoff whether she submitted votes herself, or that her own Part 1 decision was optimal. This captures a group decision process in which each member of a team has a common interest in the quality of the group's decision.

Note that although the incentives in committees are very different from those in parimutuel betting, the performance metric, θ , is calculated in an identical way as a function of subjects' institutional decisions. Just as in betting, if there is no self-selection (if all participants submit the same number of votes for their choices), this will just be equal to the raw optimality rate in the committee. However, if only optimal decision makers vote, the performance metric will be equal to one.

2.4 Measuring Confidence

Throughout the paper, confidence is defined as the strength of belief in (the probability assigned to) the ex-ante optimality (rationality) of one's decision. We implement simple binary notions of optimality, such that a given Part 1 answer can unambiguously be classified as objectively correct or false.

In principle, there are two different designs in which subjects' confidence can be elicited. First, one could elicit confidence from the same set of subjects that also make institutional decisions ("within-subjects design"). Second, one could elicit confidence in a "between-subjects design," in which those subjects who report their confidence never make any institutional decisions, and vice versa. The two potential designs each have strengths and weaknesses. A within-subjects design has the advantage that it allows the researcher to directly observe the individual-level link between confidence and institutional behavior. This is important because a main assumption underlying this paper is that institutional decisions indeed at least partly reflect confidence. At the same time, a within-subjects design has the disadvantage that it potentially introduces consistency concerns: subjects may make institutional decisions that are in line with their previously-stated confidence not because this is what they truly desire but because they desire to appear consistent vis-a-vis the experimenter.

On the other hand, a between-subjects design introduces non-trivial measurement error. If we relate the institutional improvements observed in one sample of subjects with the confidence-performance correlations observed in another, the correlation will be attenuated in any finite sample because of the attempt to link behaviors from two different groups of people. Moreover, a between-subjects design does not allow us to observe the individual-level link between confidence and institutional action. Given these considerations, we implement both types of experiments; see Table 2 for an overview of the resulting treatment design.

Between-subjects design. For this we run an additional treatment, *Confidence*, that follows the same outline as the institutions treatments discussed above, consisting of two parts. After each Part 1 task, the subject is asked the exact same confidence question for all 15 tasks throughout the study, which closely follows prior work (e.g., Enke and Graeber, 2021a,b). The instructions introduce the idea of an “optimal decision” to subjects, which we define as “the decision that maximizes your earnings, on average.”⁹ The confidence question then asks: “How certain are you that your decision in Part 1 was optimal?”. The instructions further clarify for subjects that they are supposed to indicate the percent chance that they think their decision was optimal. Subjects used a slider to enter a value between 0% and 100%, with no initialization for the slider, see Online Appendix Figure 10. Following the classification of confidence types offered by Moore and Healy (2008), we note that our confidence measurement is binary and therefore includes two types of confidence, “placement” (belief in one’s ability) and “precision” (confidence in the accuracy of beliefs).

A main design objective for us is to make our insights about the predictability of institutional filtering based on confidence data portable and scalable to different experiments and surveys. Thus, we designed the confidence elicitation to be as simple as possible, which means that we deliberately do not financially incentivize it. To the degree that this produces noisier data than an incentivized elicitation would, our results provide a lower bound estimate of the role of the confidence-performance correlation for institutional filtering.

Within-subjects design. Treatments *Betting Within*, *Auction Within* and *Committee Within* consisted of three parts each. In Part 1, subjects again solved a cognitive task. In Part 2, they indicated their confidence as described above (unincentivized). In Part 3, they made an incentivized institutional decision.

2.5 Incentives

Given the large variety of tasks that we deploy, the payment procedures necessarily need to differ across cognitive tasks. As summarized in Table 1, we can partition the cognitive tasks into three sets: (i) those that have a natural implied game payoff, such as the profit from one’s bid in the acquiring-a-company game; (ii) tasks that have an objectively correct (rational) solution and that feature discrete response options, such as Wason’s

⁹In our main experiments, the confidence elicitation screen for each task additionally specifies the definition of “optimal.” For example, in the Knapsack problem, the elicitation screen specifies that “Your decision is optimal if it maximizes your earnings.”, while in the balls-and-urns belief updating task we specify that “Your decision is optimal if it corresponds to the statistically-correct option given the information you are provided.” We implemented a robustness treatment in which we measure confidence without this additional explanation, with effectively identical results.

Table 2: Overview of experimental treatments

Treatment	Elicitations	No. of subjects
<i>Betting</i>	Cognitive task; parimutuel betting	387
<i>Auction</i>	Cognitive task; discriminatory auction	323
<i>Committee</i>	Cognitive task; committee voting	337
<i>Confidence</i>	Cognitive task; confidence	334
<i>Betting Within</i>	Cognitive task; confidence; parimutuel betting	105
<i>Auction Within</i>	Cognitive task; confidence; discriminatory auction	105
<i>Committee Within</i>	Cognitive task; confidence; committee voting	104

Notes. The table lists the main treatments that are used for empirical analyses throughout the paper. Further robustness treatments are reported throughout the paper as they become relevant.

selection task; and (iii) tasks that have a rational solution and (nearly) continuous response scales, such as a balls-and-urns belief elicitation experiment. As a result, we also deploy three types of scoring rules. Based on the insight of Danz et al. (2020) that simple scoring rules are most effective in inducing truth-telling, our overarching goal was to keep the incentive structure relatively simple and transparent. Online Appendix F provides the details for each task.

In tasks of type (i), payoffs follow immediately from the description of a game. In tasks of type (ii), subjects received 100 ECU if their response was correct and nothing otherwise. In tasks of type (iii), we deployed simple linear scoring rules with maximum payoffs of 100 ECU, such as $\pi = \max\{100 - 3d; 0\}$, where d is the distance between the subject's guess and the rational response. In total, subjects in the *Confidence* treatment made 15 incentivized decisions, while subjects in the other conditions made 30 incentivized choices. For each subject, one randomly selected decision was paid out.

Treatments *Betting*, *Auction*, *Committee* and *Confidence* were implemented at the same time and subjects were randomized into these four treatments. To investigate whether our results are sensitive to financial incentives, we implemented our experiments with two slightly different stake sizes. 596 subjects took part in the experiment with an exchange rate of \$5 per 100 ECU earned, while for the remaining 785 subjects it was \$10 per 100 ECU. Given that we do not find significant differences in rates of optimality in Part 1 or in correlations between Part 1 and Part 2 decisions across these two sets of subjects, we pool the data in what follows. We did not pre-register predictions about the potential effects of the stake size variation. Treatments *Betting Within*, *Auction Within* and *Committee Within* were likewise randomized within experimental sessions with a stake size of \$5 per 100 ECU earned.

2.6 Optimality and Confidence

Given the wide variety of cognitive biases that we study, many formal features of the underlying tasks (response scale, incentive structure, stochasticity of the environment) vary. We here discuss why this is irrelevant from the perspective of our objective of measuring the confidence-performance correlation.

First, we opted for a binary definition of optimality that allows us to use the same performance metric across tasks. Through pilots, we verified that none of our tasks generates a large mass of responses close-to-but-different-from the optimal response. Thus, the results are virtually identical if we instead code responses within a small window around the optimal response as optimal. Nonetheless, the requirement that a response be exactly optimal is more demanding in tasks that have continuous response scales rather than a discrete (e.g., binary) response scale. This might affect optimality rates in a task. However, this is fine for our purposes because our interest is not variation in the *level* of performance (or confidence) across tasks but instead in the *confidence-performance correlation*. For example, it is likely the case that subjects' confidence is mechanically higher in tasks that have response scales with only a few potential response options, yet for the same reason optimality rates will also be higher.

Second, and relatedly, the steepness of the incentives varies with the cardinality of the response scales and other features of the tasks. Again, this may affect the level of performance, but our interest is only in the confidence-performance correlation.

Third, some tasks are deterministic, while others have stochastic environments. When a task has a stochastic state, we elicit confidence about the ex-ante optimality of the decision. Thus, confidence always captures the *perceived proficiency of solving a task given the available information*, rather than imperfect information at the time of the decision. As a result, confidence always applies to the same notion of ex-ante optimality. Notice that this implies that confidence is different from the variance of one's beliefs. For instance, it is perfectly possible for a person to be fully confident that her beliefs are Bayesian, even when those beliefs exhibit strictly positive variance.

2.7 Logistics

All experiments were conducted on Prolific. We pre-registered that our experiments would be conducted using Prolific's "representative sample" option. However, this considerably slowed down data collection, so that we quickly switched to Prolific's general respondent pool. Average earnings in our experiments were \$11.82 for a study that took 33 minutes, on average. Depending on the treatment, this includes a \$4–6 participation fee. These average earnings are considerably higher than an hourly wage of \$9.60 that is recommended by Prolific. All experimental data were collected in June 2021.

We took two steps to ensure high data quality. First, the initial screen in the study consisted of an attention check. Second, subjects in all treatments completed a comprehension check that consisted of four questions. Any prospective participant who failed the attention check or answered one or more comprehension checks incorrectly was immediately routed out of the study and does not count towards the number of pre-registered completes. See Online Appendix F for the comprehension check questions in all treatments.

We pre-registered two aspects of our experiments at <https://aspredicted.org/hg4zi.pdf>. First, we pre-registered that we would sample 1,400 subjects across our four between-subjects treatments, with random assignment within each experimental session. Because slightly fewer subjects passed our comprehension checks than we anticipated, our final sample for the between-subjects treatments consists of 1,381 subjects. Second, we pre-registered that we would conduct three types of analyses: (i) the performance improvement that is caused by an institution, (ii) the relationship between confidence and institutional choices across tasks and (iii) the extent to which the correlation between performance and confidence predicts for which tasks we observe larger institutional improvements.

3 Framework and Hypotheses

This section lays out a simple empirical framework. The purpose of this framework is to derive hypotheses for our experiment and provide guidance for our analysis, rather than to serve as a general micro-founded model of how confidence determines behavior across institutional environments.

Self-selection and institutional filtering. Suppose that each of N agents forms a judgment about the solution to a cognitive task. Agent i 's solution is optimal (correct), $X_i = 1$, with probability p_i and incorrect, $X_i = 0$, with probability $(1 - p_i)$. Aggregate pre-institutional performance in the cognitive task is given by the raw rate of optimality in the N -agent cohort: $\Theta^{pre} = \frac{1}{N} \sum_i X_i \in [0, 1]$. Θ^{pre} is a random variable with mean $\theta^{pre} \equiv \mathbb{E}[\Theta^{pre}] = \frac{1}{N} \sum_i p_i$. The agents next participate in a social institution, making an institutional decision, $k_i \in [0, 1]$. These decisions represent bids in auctions, bets in betting markets and number of votes in committees. This institutional decision, k_i , is a measure of the agent's degree of self-selection into the institution: a higher k_i means that the institutionally determined outcome will be more strongly affected by the optimality of agent i 's own task response.

Let $\Theta^{post} \in [0, 1]$ be a performance metric produced by the institution (e.g., the vote share for the optimal option, the price of the ex post optimal security etc.), and let

$\theta^{post} \equiv \mathbb{E}[\Theta^{post}]$ denote the mean of that metric. We can compare this to the same metric calculated under the assumption that no self-selection occurs (i.e., $k_i = k_j, \forall i, j$). In our setting, this is just equal to θ^{pre} , the raw rate of optimality in the cohort. We define $\mathbb{G} = \theta^{post} - \theta^{pre}$ as a measure of “expected institutional filtering” due to self-selection. It will be positive if institutions produce performance metrics *as if* the population of participants are more rational than they actually are.

This institutional filtering depends on the distribution of self-selection in the population. The way this dependence works varies slightly across the institutions we consider. As discussed in Section 2.3.2, for *Betting* and *Committees* the metric of interest is

$$\theta_{bet,com}^{post} = \frac{\sum_i k_i p_i}{\sum_i k_i}. \quad (5)$$

In *Betting*, θ^{post} corresponds to the expected price produced by the parimutuel betting institution for an asset linked to the optimal decision; in *Committee*, θ^{post} is the expected vote share for the optimal decision. Institutional filtering is given by

$$\mathbb{G}_{bet,com} = \theta_{bet,com}^{post} - \theta^{pre} = \frac{\sum_i p_i (k_i - \bar{k})}{N \bar{k}}. \quad (6)$$

This expression directly depends on self-selection: it is positive if and only if the better-performing agents bet more or submit more votes, i.e., if those with higher p_i bet more or submit more votes than the average subject in the cohort.

For auctions, institutional performance is the optimality rate of the subset Ω of decision makers who won the auction. The expected institutional gain follows as:

$$\mathbb{G}_{auc} = \theta_{auc}^{post} - \theta^{pre} = \frac{1}{|W|} \sum_{j \in \Omega} p_j - \frac{1}{N} \sum_i p_i. \quad (7)$$

Thus, the auction leads to an improved aggregate outcome if the winners of the auction on average exhibit better expected performance on the task.

Self-selection and confidence. The above shows that institutional filtering ($\mathbb{G}$) is *proximally* shaped by self-selection, k_i . Our hypothesis is that this institutional filtering is *ultimately* shaped by the confidence in one’s decisions, c_i . Under this assumption, two relationships are crucial:

1. The relationship, β , between confidence, c_i , and expected task performance, p_i .
2. The relationship, ω , between confidence, c_i , and institutional decisions, k_i .

Our experiment allows us to empirically measure both of these relationships, and to

relate them to the efficacy of institutions at reducing bias. Suppose for simplicity that confidence is linearly related to decision quality as follows:¹⁰

$$c_i = \alpha + \beta \cdot p_i \quad (8)$$

Rather than viewing eq. (8) as a behavioral micro-foundation of confidence statements, we interpret it as a linear approximation of the aggregate relationship between subjective confidence and expected performance, akin to standard calibration curves. Throughout the paper, we refer to the relationship between confidence and performance as *confidence-performance correlation*. Average overconfidence (in this setting a metric which combines overestimation and overprecision), $d \equiv \bar{c} - \bar{p} = \alpha + (\beta - 1)\bar{p}$, is a function of both α and β .

The expression in eq. (8) highlights that confidence could be miscalibrated in two distinct ways. First, even if performance and confidence change one-for-one ($\beta = 1$), there may be average over- or underconfidence, $d \neq 0$. Second, even if there is no average over- or underconfidence ($d = 0$), variation in confidence across individuals might imperfectly reflect actual variation in underlying performance, $\beta \neq 1$. Here, a negative relationship, $\beta < 0$, implies that better-performing agents are, on average, *less* confident. Our main observation will be that β is essential for predicting whether or not a social institution filters biases.

Next, suppose that institutional self-selection has an approximately linear relationship with confidence:

$$k_i = \omega \cdot c_i \in [0, 1]. \quad (9)$$

Here, ω captures the degree to which self-selection, k_i , actually depends on confidence as opposed to other considerations. For instance, as discussed below, institutional decisions may be partly governed by risk aversion or higher-order beliefs about others' confidence.

These relationships allow us to derive a pre-registered prediction about the relationship between institutional filtering ($\mathbb{G}$) and a summary statistic of the distribution of confidence.¹¹

Prediction 1. (i) *If the within-task relationship between performance and confidence is positive ($\beta > 0$), institutional performance improvements are positive ($\mathbb{G} > 0$).* (ii) *In-*

¹⁰Both this formulation for c_i and the one for the institutional action k_i below are linear approximations that will fail close to the boundaries of zero and one. We choose this modeling strategy purely for the sake of simplicity. Going forward, we assume that α , β and ω are all such that $c_i \in (0, 1)$ and $k_i \in (0, 1)$.

¹¹All predictions that we state depend crucially on the assumption that $\omega > 0$, i.e., that more confident agents make more intensive institutional choices, which we test and strongly confirm below. In the following predictions, we also make the weak assumption that $\alpha > 0$, which says that, for an objective probability of being correct of zero, people's average subjective probability that they are correct is strictly larger than zero.

stitutional performance improvements, $\mathbb{G}$, increase in the within-task correlation between performance and confidence, β .

The prediction holds strictly for *Betting* and *Committee*. In these institutions, the precise number of submitted bets or votes matters for the institutional outcome. The prediction holds weakly for *Auction* because only the ordering of bids matters in that case. All proofs are relegated to Appendix B.

Much of the prior literature focuses on average overconfidence (average overestimation and/or overprecision) in a task. In contrast, our prediction highlights that the degree to which self-selection produces institutional improvements depends on the *confidence-performance correlation* across agents (the slope between confidence and performance). The following prediction clarifies the role of average overconfidence (again, here, a statistic that combines overestimation and overprecision). In contrast to the first prediction above, this one was not pre-registered, but we test it in ancillary analyses for the sake of completeness.

Prediction 2. *The effect of mean overconfidence, d , on institutional performance improvements, $\mathbb{G}$, is ambiguous. Specifically, (i) there is no relationship in Auctions; and (ii) in Betting and Committees, the effect can be positive or negative. If $\beta > 0$, the effect of an increase in d is weakly negative.*

As we will see below, while our cognitive tasks differ widely in β (with some positive and some negative), the average correlation is positive. We therefore expect a weak negative relationship between average overconfidence and institutional filtering. To see the intuition for why average overconfidence should not exhibit a clear relationship with institutional filtering, consider the auction. Suppose that the confidence of all agents was exogenously increased by the same amount, such that average overconfidence increases. Then, the bid of all agents will also increase by the same amount. This, however, does not change the resulting allocation, which only depends on who bids more rather than on how much. In *Betting* and *Committees*, the intuition is a bit more involved because the parimutuel market price and the average vote share are not linear in people's bets and votes. As a result, a uniform confidence shift can under certain conditions lead to a performance decrease (if the confidence shift implies that the bets and votes of more error-prone people increase more strongly in percentage terms).

Variation across institutions. It is conceivable that the importance of the confidence-performance correlation for filtering out errors varies across the different institutions that we study. For instance, in committee voting, higher-order beliefs about the cognitive performance and confidence of others are important components of the strategic

environment and should theoretically compete with an agent's own confidence in shaping her institutional choices. Similarly, in parimutuel betting, the mapping between bets and confidence may vary due to heterogeneous tolerance for risk. All of these mechanisms could lead ω to differ across institutions, such that the confidence-performance correlation matters more in some than in other institutions.

At the same time, there are also two reasons to expect that theoretical differences in the strategic environments across institutions do not translate into differences in how much confidence-performance correlation matters. First, we designed our experiments with the objective in mind to keep the institutions and self-selection decision as simple and similar as possible. For instance, in all three institutions, subjects' decision is essentially given by navigating a slider between 0 and 100 to indicate how intensively they would like to act in the market / auction / committee. It is plausible that this design choice attenuates or even eliminates differences across institutions.

Second, there is much evidence from experimental game theory that suggests that people often do not engage in the type of higher-order thinking that could generate variation in ω across institutions. Indeed, it is not obvious why, in practice, people would exhibit the cognitive sophistication to solve for the equilibrium of an institutional mechanism in Part 2 if they don't have the cognitive sophistication to solve the Part 1 cognitive task in the first place. It is therefore ultimately an empirical question whether and how institutions differ in the filtering they produce, and how this depends on the confidence-performance correlation.

4 Institutional Improvement Across Cognitive Tasks

Unsurprisingly, the cognitive task performance and institutional improvements observed in the between-subjects and the within-subjects treatments are very similar to one another. For the sake of brevity, we here present the results from the between-subjects treatments and always refer the reader to corresponding analyses for the within-subjects treatments in the Online Appendix.

4.1 Performance Across Tasks and Subjects

The average of optimal Part 1 responses across all tasks in treatments *Betting*, *Auction*, *Committee* and *Confidence* is 28%. Figure 1 shows sizable variation in the performance across the 15 cognitive tasks. While the optimality rates for 9 out of 15 tasks is clustered between 14% and 30%, the total range spans from <10% to >80%.¹² Online Appendix

¹²Online Appendix Figure 25 provides an analogous analysis for the within-subjects treatments.

Figure 1: Fraction of optimal responses in a cognitive task (Part 1 decision), separately for each task in treatments *Betting*, *Auction*, *Committee* and *Confidence*. $N = 1,381$ participants completed each of the 15 tasks in individually randomized order. The tasks and the corresponding definitions of an optimal response are described in Appendices A and F. Whiskers indicate standard errors of the binomial mean. See Table 1 for task codes.

Figure 13 provides a complementary subject-level perspective by showing a CDF of the number of optimal Part 1 decisions per subject.

4.2 Which Errors do Social Institutions Filter?

Recall from Section 3 that institutions will tend to filter out errors if participants who get a Part 1 task wrong bet less, bid less, or submit fewer votes in Part 2. Figure 2 shows cumulative distribution functions (CDFs) for Part 2 choices (k_i), separately for subjects who did (“optimal”) and who did not (“suboptimal”) solve the corresponding Part 1 task optimally. Pooling across the 15 cognitive tasks, the CDF of optimal responses always first-order stochastically dominates that of suboptimal responses in all three institutions. The average difference in institutional decisions is slightly more pronounced in *Betting* (64.8 average bet for optimal Part 1 decisions and 47.4 for suboptimal, a difference of 37%) than in *Committee* (75 average votes for optimal vs. 57.9 for suboptimal, 29%), or *Auction* (56.4 average bid for optimal vs. 43.6 for suboptimal, difference of 29%).¹³

These patterns immediately imply that, on average across tasks, self-selection is positive: all of our institutions filter errors to some extent. Our primary interest, however, is *in which tasks* institutions lead to a performance improvement, and by how much. To this effect, Figure 3 shows institutional improvements in performance, separately for each cognitive task. We calculate the percentage point improvement in, for example, market prices in the betting market, relative to the counterfactual in which no selection occurs (which, recall, is simply equal to the raw Part 1 optimality rate in each of our

¹³Online Appendix Figure 26 provides an analogous analysis for the within-subjects treatments.

Figure 2: Institutional choices (Part 2 decisions), split by whether the response to the corresponding cognitive task (Part 1 decision) was optimal. For each institution, empirical cumulative distribution functions are displayed. The tasks and the corresponding definitions of an optimal response are described in Appendices A and F. Based on $N = 4,845$ Part 2 decisions in the *Auction* condition, $N = 5,805$ in *Betting* and $N = 5,055$ in *Committee*, pooled across 15 different cognitive tasks. The fraction of optimal Part 1 decisions is 29% in *Betting*, 28% in *Auction* and 28% in *Committee*.

institutions). To take a simple example, suppose that in a given task the Part 1 optimality rate is 50%. Further suppose that, in the committee institution, those five subjects that got the task right each submit 100 votes, that one subject that got the task wrong also submits 100 votes and that all other subjects submit no votes. In this example, the institutional improvement is given by $(500/600 - 0.5) \cdot 100 = 33$ percentage points.

An immediate takeaway from Figure 3 is that there is large variation in improvement rates across tasks for all institutions. For example, in EGB (exponential growth bias) and IR (iterated reasoning / backward induction), aggregate error rates decrease substantially in all institutions, but they do not get filtered or even amplify in tasks such as EQ (equilibrium reasoning), AC (acquiring-a-company), RM (regression to the mean), BRN (base rate neglect) or CN (correlation neglect).¹⁴

These patterns suggest that the relationship between Part 1 responses and Part 2 behavior – *who* self-selects in institutional decisions – varies substantially across tasks. In some tasks, selection is positive, meaning that it is mostly people who make suboptimal decisions that select out. In other tasks, however, optimal and suboptimal decision makers make roughly the same Part 2 decisions, such that selection can even be negative. Indeed, the within-task correlation between bids/bets/votes and optimality ranges

¹⁴Online Appendix Figure 27 provides an analogous analysis for the within-subjects treatments.

Figure 3: Performance improvement through institutions across tasks. Percentage point improvement is computed as the aggregate performance of the institutional summary statistic minus the raw fraction of optimal responses in a cognitive task. The institutional summary statistics are given by the parimutuel market price in *Betting*, the average rate of bias among the set of winners in the *Auction* and the vote share for the optimal decision in *Committee*. The aggregate performance is based on 10,000 randomly constructed ten-subject cohorts for each institution, taking the mean over all samples. Based on $N = 323$ participants in the *Auction* condition, $N = 387$ in *Betting* and $N = 337$ in *Committee*. One-standard error bars are conservatively calculated as the ratio of the standard deviations of improvements over these random cohorts divided by the square root of the number of cohorts available in the dataset (e.g., $387/10=38.7$ in *Betting*). See Table 1 for task codes.

from $r = -0.12$ in Acquiring-a-Company (AC) bets to $r = 0.49$ in Exponential Growth Bias (EGB) bets, see Online Appendix Figure 16.

Although there is some variation in which tasks are most and least improved across institutions, there is for the most part strong agreement. If a given cognitive bias does or does not get filtered to a great degree by one institution, then it also does or does not get filtered to a great degree in the other institutions. The pairwise correlations in improvements between institutions range from 0.85 to 0.91. This striking commonality across different institutions suggests that the differential patterns of institutional filter-

ing across cognitive biases is not driven by random noise or institutional peculiarities. Rather, the uniformity of results suggests that the across-task variation in institutional filtering is rooted in characteristics of the biases themselves.

Efficiency of institutions. Our main measure of institutional improvement is a measure of *absolute* improvement. An alternative is to consider the efficiency of institutions in reducing biases: *what fraction of the theoretically possible improvement* is realized, given the actual distribution of performance. This measure is of interest because in our institutional groups of ten subjects each, it will sometimes happen that even if a social planner selected the most competent players, the post-institution performance would not be 100% because not enough subjects actually get the task right. In *Betting* and *Committee*, at least one out of ten subjects needs to get a task right in order for the theoretically possible post-institutional performance to be 100%, yet this is not always the case. In *Auctions*, we awarded the right to a bonus to five out of ten participants, so that the institutional performance metric can only equal one if at least five participants get a task right, which happens relatively rarely. To account for this, we compute an efficiency metric of improvement. This measure is given by the fraction of the theoretically possible improvement (given the distribution of performance among subjects) that is actually achieved by an institution.

Online Appendix Figure 14 shows that the efficiency of the institutions in reducing bias also strongly varies across tasks. For example, in the *Auction* treatment, the institution’s efficiency ranges from -0.15% for acquiring-a-company to 0.70% for iterated reasoning. We conclude from this exercise that the efficiency of canonical economic institutions strongly depends on the particular cognitive bias.

5 The Role of the Confidence-Performance Correlation

5.1 Confidence Across Subjects and Tasks

Pooling across all 15 cognitive tasks in treatment *Confidence*, we find that optimal decisions are associated with higher confidence. Average confidence in the pool of optimal decisions is 76%, while it is 64% in the pool of suboptimal decisions, see Online Appendix Figure 15. As in previous work, we find that individual-level heterogeneity in confidence is correlated with demographics, see Online Appendix Table 4: (i) people are overconfident on average; (ii) men are more overconfident than women; and (iii) subjects with lower performance are more overconfident than those with high performance (the “Dunning-Kruger effect”, Kruger and Dunning (1999)). These familiar correlations suggest that we are effectively measuring confidence using our unincentivized question.

Figure 4: Within-task correlation between the optimality of a response to a cognitive task (Part 1 decision) and stated confidence, separately for each task in treatment *Confidence*. Displayed are Pearson correlation coefficients, based on $N = 334$ participants. The definitions of an optimal response in each task are provided in Online Appendix A. Whiskers indicate standard errors of the estimated correlation coefficients. See Table 1 for task codes.

Our main interest, however, is not in the rate of overconfidence in the population. Rather, based on our theoretical framework, our main interest is in the variation of the performance-confidence correlation. Figure 4 shows the within-task correlation between Part 1 optimality and Part 2 confidence across our 15 tasks. We see large variation across tasks. In no task is the Pearson correlation coefficient north of $r = 0.5$, and in six tasks the correlation is actually *negative*, meaning that, if anything, sub-optimal respondents tend to be *more* certain that they solved the task correctly. This is true in particular for RM (misattribution of regression to the mean) and TM (thinking at the margin rather than the average in a tax minimization problem), for which we can statistically reject the hypothesis of no correlation between confidence and optimality. Online Appendix Figure 28 presents an analogous analysis for the within-subjects treatments.

Measurement error. As in any experiment with a finite sample, some of the across-task variation in the confidence-performance correlation that is displayed in Figure 4 will reflect measurement error. The figure clarifies this by displaying standard errors of the estimated correlation coefficients between confidence and optimality.

Because we view the documentation of across-task differences in the confidence-performance correlation (and its predictive power for institutional filtering) as one of the main contributions of this paper, we investigate through simulations how likely it is that the entirety of the variation across tasks could be spurious and driven by random noise. To this effect, we implement the following procedure. In treatment *Confidence*, we take as given the empirical marginal distributions of both confidence and optimality in each task. We then randomly scramble these two variables such that, in expectation, in each task, the confidence-optimality correlation is identical and equal to zero (what matters is not that the expected confidence-performance correlation is zero in all tasks, only that it is identical across tasks). Because in any given simulation the actual confidence-optimality correlation in any given task will not be zero (due to the finite sample of 334 subjects), these simulations tell us what degree of across-task variation in the confidence-optimality correlation will purely result from noise in finite samples. We implement this procedure 10,000 times and analyze how the resulting distribution of across-task variations compares to our actually observed across-task variation. Specifically, we consider how the observed across-task standard deviation (and range) of the confidence-optimality correlation compares with the simulated distribution. Online Appendix Figures 17 and 18 show the details. We find that the empirically observed standard deviation and range are substantially larger than in every single simulation. This suggests that the probability that random noise generates the entire across-task variation in Figure 4 is essentially zero.

5.2 The Confidence-Performance Correlation and Institutional Improvement

Our hypothesis is that the sign and magnitude of the optimality-confidence correlation illustrated in Figure 4 is predictive of institutional improvement. As discussed in Section 2.4, this question can be analyzed in both a within-subjects and a between-subjects design. Figure 5 shows the results for both approaches.

In the left panel (between-subjects data), the vertical axis shows the magnitude of institutional improvement in percentage points, averaged across treatments *Betting*, *Auction* and *Committee*. The horizontal axis shows the within-task correlation between optimality and confidence in treatment *Confidence*. Thus, in this figure, we predict the institutional improvement observed in one sample of subjects with the confidence-performance correlation observed in another sample of subjects.

In the right panel (within-subjects data), the vertical axis and horizontal axes show the same quantities as discussed above, except that they are all derived from treatments *Betting Within*, *Auction Within* and *Committee Within*. Thus, we here predict the institu-

tional improvement observed in one sample of subjects with the confidence-performance correlation of those same subjects.

We make two main observations. First, the figures visually confirm our hypothesis. In tasks with a strong confidence-performance correlation, the institutional improvement is large. This is the case for tasks such as exponential growth bias, iterated reasoning and gambler’s fallacy. Opposite patterns hold for attribution (understanding regression to the mean), thinking at the margin, correlation neglect and equilibrium reasoning. Second, these patterns are slightly more pronounced in the within-subjects data. In the between-subjects data, the Pearson correlation between institutional improvement and the confidence-optimality correlation is $r = 0.76$, while it is $r = 0.93$ in the within-subjects data.

Note that because we generally estimate both the confidence-performance correlation and the institutional improvement with random noise, the patterns displayed in Figure 5 are likely to be attenuated relative to their true magnitudes by standard measurement error arguments. Indeed, as discussed in Section 2.4, through this lens it is also unsurprising to see that the visual link between confidence-performance correlation and institutional improvement is stronger in the within-subjects treatments because in any finite sample the between-subjects approach necessarily introduces additional measurement error relative to the within-subjects treatments because institutional improvement and confidence-performance correlation are observed in different samples of people. In any case, as we hypothesized, the relationship between institutional improvement and confidence-performance correlation is always strong.

Variation across institutions. An immediate question is whether the predictability of institutional improvement through the confidence-performance correlation is similar across the different institutions that we study. For both the between- and the within-subjects data, we find that this is indeed the case. The correlations between institutional improvement and confidence-performance correlation are $r^{\text{auction}} = 0.69$, $r^{\text{betting}} = 0.73$, $r^{\text{committee}} = 0.77$, $r^{\text{auction within}} = 0.9$, $r^{\text{betting within}} = 0.9$ and $r^{\text{committee within}} = 0.91$, see Online Appendix Figures 20 and 30. There are two different interpretations of this similarity across institutions, both of which we embrace. A first is that this result is surprising because – from a theoretical perspective – it is conceivable that confidence matters to a different quantitative degree in some institutions than in others. A second interpretation, however, is that this similarity is unsurprising because we specifically designed the institutions to be as simple as possible, including that the self-selection decision is very similar implementation-wise across institutions (a slider between 0 and 100).

Figure 5: Confidence-performance correlation and institutional improvement. The left panel shows the results for the between-subjects treatments and the right panel those for the within-subjects treatments. In the left panel, the horizontal axis shows the within-task correlation between confidence and optimality in treatment *Confidence*. The vertical axis shows the average institutional improvement across treatments *Betting*, *Auction* and *Committee*. In the right panel, we show analogous quantities, except that they are all derived from treatments *Betting Within*, *Auction Within* and *Committee Within*. Percentage point improvement is computed as the aggregate performance of the institutional summary statistic minus the raw fraction of optimal responses in a cognitive task, averaged across institutions. The institutional summary statistics are given by the parimutuel market price in *Betting*, the average rate of bias among the set of winners in the *Auction* and the vote share for the optimal decision in *Committee*. The aggregate performance is based on 10,000 randomly constructed ten-subject cohorts for each institution, taking the mean over all samples. See Table 1 for task codes.

Mechanism: Confidence and institutional self-selection. Our hypothesis for why the confidence-optimality correlation is so strongly predictive of the magnitude of institutional improvement is that more confident subjects are more likely to behave aggressively in the institution: that they bet less, bid lower amounts, and submit fewer votes. Through the lens of our conceptual framework in Section 3, this amounts to saying that $\omega > 0$. In our within-subjects treatments, we can directly test this assumption. Online Appendix Figure 29 shows binned scatterplots of institutional actions against stated confidence separately for each institution. We find that the correlations between confidence and bids, bets and votes are $r = 0.79$, $r = 0.85$ and $r = 0.89$, respectively.¹⁵ In our between-subjects treatments, subjects never both report their confidence and make an institutional decision, such that it is impossible to report the correlation.

¹⁵Online Appendix Figure 19 shows that confidence and institutional action are strongly correlated not just across individuals but also across cognitive tasks: in those tasks in which subjects are on average more confident, they also bet / bid / vote more intensively, on average.

Predictability of efficiency of institutions. Our main analysis considers absolute institutional improvement. In Section 4, we additionally introduced a measure that gauges the efficiency of institutions in reducing bias, relative to how much it could reduce bias given the distribution of performance in the population. A natural question is whether the confidence-performance correlation is also predictive of institutional efficiency. Online Appendix Figure 21 shows that the confidence-performance correlation turns out to be an even stronger predictor of efficiency, with r rising to 0.87 in the between-subjects data and to $r = 0.94$ in the within-subjects data.

Robustness: Sensitivity to outliers. To examine whether our finding is driven by specific tasks, we perform a leave-two-out analysis: we compute 10,000 correlation coefficients, in each run excluding two randomly selected tasks. The resulting distribution of correlations confirms that the result is not driven by individual tasks. In the between-subjects treatments, the Pearson correlation coefficients vary between 0.61 and 0.83 when pooling all institutions, with a mean of 0.76. In the within-subjects treatments, they vary between 0.86 and 0.98, with a mean of 0.93.

5.3 Which Types of Errors Have Strong Confidence-Performance Correlation?

Our results raise the question of *what characteristics* of tasks make decision makers' beliefs more predictive of their performance? The broader question of how people's self-awareness of their own errors varies across different cognitive tasks has received a fair amount of attention in the literature, such as in the hard-easy effect or the "bias blind spot" literature in psychology. However, this body of work focuses on how average overconfidence (or average overplacement) vary across tasks. For our purposes, the relevant object of interest is, instead, the performance-confidence correlation.

Given that we are looking at a moderately-sized sample of tasks, an analysis of this question is naturally very tentative in nature and ought to be interpreted with care because, with relatively few data points, one faces the risk that any "theory" will overfit the data. Still, a natural starting point is the role of misleading intuitions. Many "classical" task paradigms in the decision-making literature are associated with a compelling, yet flawed intuition, such as in the CRT (e.g., Kahneman, 2011). Other tasks, such as backwards induction, constrained optimization in the Knapsack problem or the acquiring-a-company task arguably do not elicit similarly strong intuitions. Instead, we can arguably loosely think of these errors as "complexity-driven." There are reasons to hypothesize that the confidence-performance correlation will be less accurate for intuition-based biases. Indeed, a long literature in psychology on processing fluency and the "feeling of

rightness” (e.g., Thompson, 2009; Thompson et al., 2011) posits that flawed intuitions are particularly misleading if they are associated with the experience of high confidence.

In the absence of an established definition of the strength of misleading intuitions in a problem, we construct a proxy by looking at the mass of responses on the modal suboptimal answer.¹⁶ According to this classification, a task is more likely to generate a false strong intuition the larger the number of people who choose the exact same wrong answer (conditional on being wrong). For instance, in the CRT or correlation neglect, large fractions of people produce exactly the same wrong answer, while in exponential growth calculations that is not the case. We construct this measure only for those nine tasks for which there are more than ten possible responses. This is because if there are only two or three response options, it is impossible to disentangle whether people jump to a specific wrong solution because of a misleading intuition or because of, e.g., random judgment noise.

Online Appendix Figure 22 provides some tentative evidence that tasks in which wrong responses are strongly peaked (“intuition problems”) see somewhat smaller confidence-performance correlations, though the results are a bit mixed. For example, in correlation neglect and balls-and-urns belief updating, about 50% of all responses are concentrated on a single answer, and the optimality-confidence correlation in these tasks is roughly zero. In iterated reasoning, exponential growth bias and the Knapsack problem, on the other hand, the fraction of concentrated responses is between 10% and 30%, and the within-task optimality-confidence correlation in these tasks is always strictly positive.

We acknowledge that this analysis is tentative in nature, for at least three reasons. First, it is based on only nine tasks. Second, it ignores that the response scales across these nine tasks differ widely. Third, the results using the peakedness measure are relatively noisy. Future research is needed to shed more light on the determinants of the quality of the confidence-performance correlation.

5.4 The Role of Average Overconfidence

Our conceptual framework in Section 3 accounted for two forms of potential miscalibrations in the distribution of confidence: (i) for a given average level of confidence, the correlation between confidence and optimality (β) could be less than one; and (ii) for a given β , average confidence could be too high or low, $d \neq 0$. In this section, we empirically explore the potential implications of average over- or underconfidence for institutional filtering.

¹⁶Relatedly, there is some evidence from the psychology literature that the confidence-performance correlation is high in those tasks that produce correct answers and low in tasks that tend to produce incorrect answers (the “consensuality” principle). See, e.g., Koriat (2008, 2012).

Appendix Figure 23 plots average confidence in treatment *Confidence* against the optimization rate in each task.¹⁷ We observe two main patterns: first, there is average overconfidence in all of the 15 tasks. Second, average confidence and the optimization rate are strongly positively correlated across tasks, $r = 0.75$. As a consequence, absolute overconfidence is much more pronounced in some tasks than others. This insensitivity of confidence statements to the optimization rate mirrors previous research (e.g., Erev et al., 1994; Moore and Healy, 2008).

How does such average overconfidence relate to institutional behavior and resulting performance improvements? As discussed in Section 3, average overconfidence and the resulting more aggressive average behavior could translate into (weakly) lower institutional improvement when confidence and performance are positively correlated, $\beta > 0$. In line with this prediction, our data indeed show relatively weak negative relationships between average overconfidence (computed as average confidence minus average performance) and institutional improvement. Appendix Figure 24 illustrates the results by again averaging the institutional improvement across all institutions. The correlations between overconfidence and institutional improvement are given by $r = -0.34$ for the between-subjects experiments and by $r = -0.32$ for the within-subjects experiments (neither significantly different from zero at conventional levels).¹⁸ These results are in line with Prediction 2 from our framework in Section 3, and highlight that what matters for institutional filtering is indeed mostly the confidence-optimality correlation, rather than average overconfidence.

6 Expert Predictions

We compare our experimental results with the predictions of a sample of experts. The expert survey was conducted using the Social Science Prediction Platform.¹⁹ We distributed the survey among participants of the *CESifo Area Conference on Behavioral Economics 2021* and attendees of the online speaker series *VIBES – The Virtual Behavioral Economics Seminar*. We obtained a total of $N = 38$ complete responses in November 2021. Among those who indicated their professional level, 57% are faculty at all levels, 10% are post-doctoral researchers and 33% are graduate students. Over 85% of the sample indicated behavioral or experimental economics as their main field of expertise.

To keep the number of total predictions for each forecaster manageable, we picked

¹⁷Online Appendix Figure 31 shows the results for the within-subjects treatments.

¹⁸Regarding the specific institutions, the correlations are $r = -0.28$ for *Betting*, -0.36 for *Committee*, -0.36 for *Auction*, $r = -0.24$ for *Betting Within*, $r = -0.40$ for *Auction Within* and $r = -0.23$ for *Committee Within*.

¹⁹Public study ID *sspp-2021-0028-v1*, see <https://socialscienceprediction.org/s/b04a0x>. We thank Stefano DellaVigna and Nicholas Otis for excellent comments and support.

Figure 6: Expert forecasts and empirical analogues. The left panel plots predicted institutional improvements against actual ones, separately for each task. The right panel plots the predicted difference in confidence between optimal and suboptimal decisions against the true difference. The diagonal line indicates perfect calibration. See Table 1 for task codes.

one specific institution (*Auction*) and a subset of seven tasks.²⁰ Each expert made two separate sets of predictions for each task. First, we provided the raw optimality rate of answers to a given cognitive task and asked experts to predict the average optimality rate among the five winners of the auction. This allows us to compute predicted institutional improvement. Second, we asked experts to predict average confidence among subjects that took optimal / suboptimal decisions. This allows us to compare actual with predicted confidence-performance correlations. Screenshots of the elicitation screens are reproduced in Appendix Figures 11 and 12.

Panel A of Figure 6 plots the median forecast of institutional improvement through the auction against actual improvement. Panel B plots the predicted difference in confidence between optimal and suboptimal decision makers against the corresponding empirical counterpart. The 45-degree lines represent the hypothetical case of perfect calibration of the experts. We make four observations. First, expert forecasts track the distribution of tasks reasonably well: across tasks, higher average forecasts of institutional improvement and confidence differences tend to be associated with higher actual improvement and confidence differences. Second, average expert forecasts of improvement and confidence differences tend to be internally consistent with our framework: if one believes that confidence differences are larger than they actually are, then one

²⁰These tasks are RM, CN, TM, BRN, AC, CRT and EGB. Our expert elicitation also included WAS and BU, but due to a coding error the corresponding forecasts are not usable.

should also believe that the institutional improvement will be larger than it actually is. This good qualitative calibration of forecasts resonates with previous findings on the accuracy of expert forecasts (see, e.g., DellaVigna et al., 2019), but is accompanied by quantitative miscalibration in our data. Specifically, third, experts generally overpredict both the magnitude of institutional improvement and the magnitude of confidence differences between optimal and non-optimal subjects. Fourth, Panels A and B of Figure 6 show that the expert forecasts are excessively compressed relative to the truth: experts predict that the degree of confidence differences and institutional improvement are more similar across tasks than is actually the case.

7 Discussion

When we as experimental economists use average behavior in experiments to measure the severity of a bias, we are measuring a special case, that of no self-selection. Many of our most important and ubiquitous economic and social institutions create significant scope for self-selection out of decision-making, and this self-selection can produce rates of bias in aggregate outcomes that differ from the raw rate of bias in the population. As a result, sample means from experiments may over- or under-state the influence biases are likely to have for the aggregate outcomes produced by real-world institutions.

In this paper, we take some steps towards understanding the influence of self-selection over institutional outcomes for a wide range of biases, using maximally-simple variants of canonical institutions like speculative and allocative markets and organizations. We take a broad approach, studying 15 of the most famous and economically relevant biases from behavioral economics. We find that self-selection can have large effects on bias, but, more importantly, that the degree to which this is true varies wildly across distinct biases. We show that this heterogeneity is strongly related to heterogeneity in the predictiveness of subjects' beliefs about their own decision quality: the correlation between performance and confidence in the population.

Though our experiment takes a wide-ranging approach, we view it as a piece of a broader agenda. We here summarize implications and limitations of our work in order to help inform future research on the topic.

Limitations. We deliberately studied only the simplest variants of institutions, and designed the self-selection decision to be operationally extremely similar across institutions. This probably minimizes any latent differences in self-selection across institutional contexts. This comes at the cost that our design is not well-suited to intensively investigate how strongly institutions can differ in their scope for self-selection. We think this encourages follow-up work that implements dynamic, feedback-rich variations of

markets and organizations that allow subjects to make more sophisticated, experienced choices, allowing any latent differences across these institutions to show themselves.

A second limitation of our paper is that we do not consider the welfare effects of self-selection. Rather, we only focus on the efficiency of the aggregate quantity that an institution produces. Yet, in many contexts, it may be that self-selecting out of a market has real intrinsic costs (for example, when a person should purchase insurance but selects out of the market due to confusion). In such cases, the welfare benefits of self-selection (debiased aggregate quantities) are counteracted by the welfare costs of non-participation. Future research may helpfully study when and why which of these two effects dominates.

Methodological takeaway. Future researchers can tentatively gauge the likely impact of self-selection on the biases they measure, without undertaking the logistical challenges of implementing full-fledged social institutions. Our research suggests that simple and unincentivized measures of confidence can be used to produce an index of the susceptibility of biases to filtering by self-selection. Simply by (i) asking subjects at the end of an experiment how likely they think it is they made an optimal decision and (ii) reporting the correlation of this confidence measure with actual performance, researchers can provide evidence on how strongly self-selection should attenuate the impact of biases. We believe that this simple methodological blueprint can allow researchers to provide valuable context on the likely impact of lab-measured biases on real aggregate outcomes at very low cost.

Importance of the confidence-performance correlation. One reason why we encourage that future research on cognitive biases report the performance-confidence correlation is that, thus far, most research on confidence tends to focus on average overconfidence or overplacement, which – as we highlight here – is less relevant as a driver of self-selection than the performance-confidence correlation. We, hence, conjecture that more research energies might profitably be spent measuring and understanding this object and its sensitivity to features of the choice environment. There are at least three avenues that seem especially promising. (i) We have studied 15 salient biases from behavioral economics but there are dozens of others that could be similarly and retrospectively studied through the lens of the confidence-performance correlation. (ii) Although behavioral economists have put great energies into studying how nudges, frames, feedback, familiarity and learning influence biases themselves, we know next to nothing about how these same drivers of choice influence the confidence-performance correlation. For example, the effect of policy interventions on the confidence-performance link may be every bit as important for social science outcomes as their effect on biases themselves.

After all, casual introspection suggests that public policy might affect not only whether people make mistakes but also which people are aware of their mistakes. (iii) For future theorizing and practical predictions, it would be very useful to understand *why* it is that in some tasks people's confidence and performance are reasonably tightly linked, but not in others. Why do sometimes the "right" and othertimes the "wrong" people believe that they are getting things wrong?

ONLINE APPENDIX

A More on the Cognitive Tasks

We describe the 15 cognitive tasks in some detail here. See Appendix F for the full task instructions.

Base rate neglect (BRN). An important principle of rational information-processing is to take into account base rates, but a voluminous line of work documents that people tend to neglect base rates (e.g., Bar-Hillel, 1980; Kahneman and Tversky, 1973). We devised a simple variant of Tversky and Kahneman’s (1982) well-known taxi-cab problem, which is known to generate responses that neglect the base rate. In our problem, a quality control machine of a bike manufacturer classifies bikes as good or defective but misclassifies any given bike 25% of the time. Subjects are asked to state the percentage chance that a bike is actually defective, given that the base rate for a defective bike is 10% and that the quality control machine classifies the bike as defective. A common incorrect answer is 75%, whereas the statistically correct answer is 25%.

Correlation neglect (CN). Taking into account potential non-independence of data is a core principle of both rational belief updating and econometrics courses. We devised a simplified version of the correlation neglect task developed in Enke and Zimmermann (2019). Subjects are asked to estimate the weight of a bucket. The hypothetical characters Ann and Bob have each examined the bucket and produced an estimate. They share their estimate with Charlie, who computes the average of their two guesses. The subject has access to Ann’s estimate of 70 and Charlie’s estimate of 40. A common incorrect answer is to compute the average of 40 and 70, i.e., 55. The correct answer is 40.

Balls-and-urns belief updating (BU). A widely used paradigm to study belief updating are so-called balls-and-urns experiments. In our setup, there are two bags. One contains 70 red and 30 blue chips, and one contains 30 red and 70 blue chips. One of them gets selected at random with 50-50 chance, and a balls gets drawn from the selected bag. Subjects are asked to indicate the percentage chance that the selected bag is the one that contains more red chips, given that the drawn chip is red. Subjects commonly exhibit a conservatism bias in this setup and state posteriors strictly between 50% and 70%. The Bayesian answer is 70%.

Gambler's fallacy (GF). Following Dohmen et al. (2009), subjects were asked to predict the next outcome in the following sequence of tosses of a fair coin, where the last three tosses came up Heads: T - T - T - H - T - H - H - H . In this type of task, subjects occasionally believe that Tails is “due.” The correct answer is to select that “Both are equally likely.”

Sample size neglect (SSN). Adapting the classic “hospital problem” (Kahneman and Tversky, 1972; Bar-Hillel, 1979), subjects were asked whether a factory that produces 45 chairs each day or a factory that produces 15 chairs each day has more days on which more than 20% of chairs are defective. A common incorrect response is that this happens equally often in both factories. The correct answer, however, is that this outcome is more likely in the smaller factory.

Regression to the mean / misattribution (RM). People exhibit a well-known tendency to attribute outcomes to internal factors rather than random noise, which leads them to neglect mean reversion. In a variant of classical work on the failure to appreciate regression (Kahneman and Tversky, 1973), subjects are asked to assess whether the true IQ of a test-taker is more likely to be above or below 140, given that their IQ test score is 140, the average score in the sample is 100, and test scores reflect a combination of true ability and random chance. Subjects commonly believe that the person's true IQ is equally likely to be above or below 140. The correct answer is that the person's true IQ is more likely to be below than above 140. Such failure to account for mean reversion is a special case of a more general class of biases that reflect misattribution.

Acquiring-a-company (AC). This game is one of the most widely studied tasks in experimental economics, both because it reflects a general class of errors in contingent reasoning and because its adverse selection logic has many applications in economics, such as in auctions. Following Charness and Levin (2009), we implement a version of the AC game in which subjects play against a computerized opponent. A seller has a company that is worth either 20 or 120 points to him. The company's value to the buyer is 1.5 times as much as the value to the seller. The subject makes a take-it-or-leave-it-offer, which the seller accepts if and only if the offer is at least as high as the value of the company to him. Subjects frequently bid strictly more than the theoretically optimal bid of 20, which neglects the adverse selection logic of the problem.

Wason selection task (WAS). The Wason task (Wason, 1968) is a widely used task in the social sciences because it captures failures in contingent reasoning and a tendency towards positive hypothesis testing in a simple way. In the problem, there is a deck of

four cards that have numbers (odd or even) on one side and a color (brown or green) on the other. Subjects are tasked with turning over (only) those cards that can be useful in assessing whether the statement “All of the cards with an even number on one side are green on the other” is true. In this task, subjects frequently engage in positive testing by turning over the card with the even number and the one that is green. The logically correct choice is to pick the brown card in addition to the card with the even number.

Cognitive Reflection Test (CRT). The CRT is likewise a widely studied task in economics because it effectively captures the intuitive “System 1” responses that the early heuristics and biases program emphasized. Moreover, responses in the CRT have been shown to be correlated with various economic behaviors (Frederick, 2005). We implement the question “It takes 6 machines 6 days to produce 6 cars. How long would it take 12 machines to produce 12 cars?” A tempting, incorrect answer is 12 days. The correct answer is 6 days.

Iterated reasoning / Backward induction (IR). To capture the well-known and widely-studied tendency to iterate the best-response function only a small number of times (“level k reasoning”), we follow Bosch-Rosa and Meissner (2020) in implementing a one-player guessing game that only requires iteration of the best response function but is independent of beliefs about others. Subjects are asked to pick two numbers between 0 and 100, inclusive. Their task is to select numbers whose average is as close as possible to $2/3$ of either number. While zero is the correct solution, most subjects state strictly positive values.

Equilibrium Reasoning / Predicting response to incentives (EQ). Many empirical regularities in behavioral economics can be understood as people failing to accurately predict others’ behavior from their incentives. One elegant demonstration of this is the experiment in Dal Bó et al. (2018), which we simplify here. Subjects are presented with two similar-looking 2×2 payoff matrices. In Game A, all payoffs are higher than in Game B, but Game B has a cooperative equilibrium, while Game A has a prisoner’s dilemma structure. Subjects are asked to predict in which game past participants made more money, on average. A majority of subjects incorrectly believes that people make more in Game A because they fail to anticipate differences in equilibrium play.

Knapsack / identifying constrained optima (KS). Knapsack problems are a simple to explain but canonical instance of constrained optimization, which lies at the heart of a large class of economic consumer and firm maximization problems (Mathews, 1896; Murawski and Bossaerts, 2016). In our implementation, subjects pick from a set of 12

items, each of which has a known value and weight. The objective is to maximize the sum of values chosen, while satisfying a budget constraint on the weights. Experiments typically show that subjects fail to identify the value-maximizing bundle (which, in our instance consists of 4 of the 12 items).

Portfolio choice (PC). Various studies have documented failures to construct efficient financial portfolios. One well-known example of this is failure is the use of the so-called $1/N$ heuristic (Benartzi and Thaler, 2001), according to which people split their investment uniformly across the available assets. To get at this, we ask subjects to choose between two portfolios that are constructed from four assets each. The portfolios are identical except that one allocates $1/4$ of the budget to each asset in a way that makes this “ $1/N$ portfolio” strictly dominated by the other available portfolio.

Thinking at the margin (TM). One of the core lessons of economics is to think at the margin rather than the average, yet people have consistently been shown to think in terms of averages. We developed a simplified version of the taxation problem in Rees-Jones and Taubinsky (2020). Subjects are tasked with deciding which of two bank accounts to allocate 20 points to. Both bank accounts already contain 40 points. The trick is that the marginal tax rate for additional 20 points is lower in the bank account that has a higher average tax rate.

Exponential growth bias (EGB). An ability to compute compound interest is essential in numerous economics models and decision contexts, including exponential time discounting, savings and investment. Following previous studies (Levy and Tasoff, 2016), we ask subjects to guess how much a stock that is worth \$100 today is worth after 20 years if its value increases 5% each year. People tend to give a response of \$200 in this problem, which entirely misses the compounding effect. The correct answer is \$265.

B Model Derivations

In the following, we derive our main predictions separately for the model of committee voting or parimutuel betting (Appendix B.1) and for the model of auctions (Appendix B.2).

B.1 Committees and Parimutuel Betting Markets

Note that expanding eq. (6) from Section 3, institutional gain $\mathbb{G}_{bet,com}$ may be expressed as:

$$\mathbb{G}_{bet,com} = \frac{\sum_i p_i (Nk_i - \sum_j k_j)}{N^2 \bar{k}} \quad (10)$$

$$= \omega \beta \frac{\sum_i p_i (p_i - \bar{p})}{N \bar{k}} \quad (11)$$

$$= \frac{(N-1)\beta}{N\bar{c}} s_p^2 \quad (12)$$

where s_p^2 is the sample variance of p . Informally, we may consider $\beta/\bar{k} = \partial \log \bar{k} / \partial \bar{p}$, as the percent increase in the average bid given an increase in the average confidence among the players.

Proof. (Prediction 1, Part (i)) Stated formally, this part of the prediction states that if $s_p^2 > 0$ and $\beta > 0$, we have $\mathbb{G}_{bet,com} > 0$. Since $\bar{c} > 0$ in our case²¹, eq. (12) immediately provides the result. $\square$

Proof. (Prediction 1, Part (ii)) This part of the prediction says that for $\alpha > 0$ and $s_p^2 > 0$, we have $\frac{\partial \mathbb{G}_{bet,com}}{\partial \beta} > 0$. Using eq. (12) we may compute

$$\frac{\partial}{\partial \beta} \mathbb{G}_{bet,com} = \frac{\partial}{\partial \beta} \frac{(N-1)\beta}{N(\alpha + \beta \bar{p})} s_p^2 \quad (13)$$

$$= \frac{(N-1)\alpha}{N(\alpha + \beta \bar{p})^2} s_p^2 > 0 \quad (14)$$

Given our assumptions the result follows. $\square$

Proof. (Prediction 2) This prediction states that the effect of an increase in average overconfidence, d , on institutional improvement, $\mathbb{G}$, is ambiguous. Formally, for the case of betting and committee voting, we predict that for $\beta > 0$ and $s_p^2 > 0$, a change in overconfidence $d \rightarrow d + \delta d$ need not imply $\Delta \mathbb{G}_{bet,com} < 0$.

²¹Aside from the empirics, $c_i > 0$ when $\alpha, \beta > 0$.

Firstly, we may compute that: $\frac{\partial \mathbb{G}_{bet,com}}{\partial \alpha} < 0$. Using eq. (12) we may compute

$$\frac{\partial}{\partial \alpha} \mathbb{G}_{bet,com} = \frac{\partial}{\partial \alpha} \frac{(N-1)\beta}{N(\alpha + \beta \bar{p})} s_p^2 \quad (15)$$

$$= -\frac{(N-1)\beta}{N(\alpha + \beta \bar{p})^2} s_p^2 < 0 \quad (16)$$

Secondly, we recall our earlier result that:

$$\frac{\partial}{\partial \beta} \mathbb{G}_{bet,com} > 0 \quad (17)$$

Noting that:

$$\frac{\partial d}{\partial \alpha}, \frac{\partial d}{\partial \beta} > 0 \quad (18)$$

and our assumptions the result follows. $\square$

B.2 Auctions

In the case of a multi-unit auction, eq. (7) showed that:

$$\mathbb{G}_{auc} = \frac{1}{|W|} \sum_{j \in W} p_j - \frac{1}{N} \sum_i p_i. \quad (19)$$

Proof. (Prediction 1, Part (i)) This part states that when $\beta > 0$, we have $\mathbb{G}_{auc} \geq 0$. Note that when $\beta > 0$, $\frac{1}{|W|} \sum_{i \in W} p_i \geq \bar{p}$. The result then follows. $\square$

Proof. (Prediction 1, Part (ii)) When $\beta > 0$, we have $\frac{\partial \mathbb{G}_{auc}}{\partial \beta} = 0$. This holds because given a fixed set of probabilities, $\{p_i\}$, the ordering of the bids is invariant under a change, $\beta \rightarrow \beta + \delta\beta$ so long as $\delta\beta > -\beta$. $\square$

Proof. (Prediction 2) This prediction states that an increase in overconfidence, d , has no effect on institutional improvement $\mathbb{G}$ when $\beta > 0$. In the case of auctions, we have $\frac{\partial \mathbb{G}_{auc}}{\partial \alpha} = 0$. This follows since given a fixed set of probabilities, $\{p_i\}$, the ordering of the bids is invariant under a change, $\alpha \rightarrow \alpha + \delta\alpha$. Furthermore, the proof of Pred. 1 part (ii) indicates that a change in β doesn't change $\mathbb{G}$ so long as β remains positive. Accordingly, for any change in average overconfidence, $\delta d = \delta\alpha + \delta\beta\bar{p}$ in which $\beta > 0$, we see that there is no institutional improvement. $\square$

Predict average confidence in the cognitive tasks

For each of the tasks shown below, please predict the average confidence separately for subjects who took the optimal decision and those who did not. Confidence was elicited by asking subjects to provide their assessment of how likely it is that their decision was optimal. 0% means “Not at all certain” and 100% means “Fully certain”.

- Click [\[here\]](#) for a reminder of the prediction task instructions and [\[here\]](#) for the study background and general instructions. Instructions will open in a new window.
- Click on the task name to see a screenshot of the actual task screen, including a definition of what “optimal” means in the respective task.

	Your prediction: Average confidence stated for answers that were optimal	Your prediction: Average confidence stated for answers that were not optimal
Wason selection task: Failure to gather valuable evidence via positive hypothesis testing bias. Adaptation of 4-card task from Wason (1968).	%	%
Balls-and-urns belief updating: Failure to calculate Bayesian posterior. Give probabilistic beliefs about which urn a colored ball is drawn from (Edwards, 1968).	%	%
Regression to the mean: Failing to account for noise in outcomes via failure to recognize regression to the mean. Adaptation of task from Kahneman and Tversky (1973).	%	%
Thinking at the margin: Thinking about average instead of marginal costs/benefits. Adaptation of marginal taxation task from Rees-Jones and Taubinsky (2020).	%	%
Acquiring-a-company: Failing to properly condition on contingencies as in the Winner's Curse. Bidding task against computer as in Charness and Levin (2009).	%	%
Exponential growth calculation: Underestimate the exponential effects of compounding. Interest rate forecasting problem adapted from Levy and Tasoff (2016).	%	%
Correlation neglect: Failing to account for non-independence of data in inference. Adaptation of tasks from Enke and Zimmermann (2019).	%	%
Base rate neglect: Ignoring base rates when computing posteriors. Adaptation of taxi-cab problem from Tversky and Kahneman (1982).	%	%
Cognitive reflection test: Following intuitive but misleading “System I” intuitions. Adaptation of one of the problems by Frederick (2005).	%	%

Figure 11: Screenshot of elicitation screen in the expert survey for forecasts of confidence.

Predict the auction-filtered optimality rate in the cognitive tasks

For each of the tasks shown below, the raw optimality rate is displayed. Please predict the **auction-filtered optimality rate**, which is the relative frequency of optimal decisions among those subjects who won the auction in a given task.

- Click [[here](#)] for a reminder of the prediction task instructions and [[here](#)] for the study background and general instructions. Instructions will open in a new window.
- Click on the task name to see a screenshot of the actual task screen including a definition of what “optimal” means in the task.

	Your prediction: Auction-filtered optimality rate (optimality rate of winners)
Wason selection task: Failure to gather valuable evidence via positive hypothesis testing bias. Adaptation of 4-card task from Wason (1968). Raw Optimality Rate: 83%	%
Balls-and-urns belief updating: Failure to calculate Bayesian posterior. Give probabilistic beliefs about which urn a colored ball is drawn from (Edwards, 1968). Raw Optimality Rate: 14%	%
Regression to the mean: Failing to account for noise in outcomes via failure to recognize regression to the mean. Adaptation of task from Kahneman and Tversky (1973). Raw Optimality Rate: 39%	%
Thinking at the margin: Thinking about average instead of marginal costs/benefits. Adaptation of marginal taxation task from Rees-Jones and Taubinsky (2020). Raw Optimality Rate: 26%	%
Acquiring-a-company: Failing to properly condition on contingencies as in the Winner's Curse. Bidding task against computer as in Charness and Levin (2009). Raw Optimality Rate: 16%	%
Exponential growth calculation: Underestimate the exponential effects of compounding. Interest rate forecasting problem adapted from Levy and Tasoff (2016). Raw Optimality Rate: 28%	%
Correlation neglect: Failing to account for non-independence of data in inference. Adaptation of tasks from Enke and Zimmermann (2019). Raw Optimality Rate: 13%	%
Base rate neglect: Ignoring base rates when computing posteriors. Adaptation of taxi-cab problem from Tversky and Kahneman (1982). Raw Optimality Rate: 19%	%
Cognitive reflection test: Following intuitive but misleading “System I” intuitions. Adaptation of one of the problems by Frederick (2005). Raw Optimality Rate: 59%	%

Figure 12: Screenshot of elicitation screen in the expert survey for forecasts of the change in optimality rate through the *Auction* institution.

C.2 Additional Figures for Between-Subjects Treatments

Figure 13: Empirical cumulative distribution of total number of optimal responses to the cognitive tasks (Part 1 decisions), across subjects in treatments *Betting*, *Auction*, *Committee* and *Confidence*. The figure pools data from all 15 tasks across all four between-subject treatments.

Figure 14: Performance improvement (efficiency measure) through institutions across tasks. Efficiency is computed as the aggregate performance rate after institutional filtering minus the the fraction of optimal Part 1 responses, all divided by the difference between the maximum possible improvement (given responses to the cognitive tasks and the structure of the institution) and the fraction of optimal responses to the cognitive tasks (Part 1 decisions). The aggregate performance rate is based on 10,000 randomly constructed 10-subject cohorts for each institution, taking the mean over all samples. Each participant completed all 15 tasks in random order. Based on $N = 323$ participants in the Auction condition, $N = 387$ in Betting and $N = 337$ in Committee. One-standard error bars are conservatively calculated as the ratio of the standard deviations of efficiencies over these random cohorts divided by the square root of the number of cohorts available in the dataset (e.g., $387/10=38.7$ in Betting). Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; EQ=Predict others' play; GF: Predict sequence of draws; IR=Backwards induction; KS=Knapsack; PC=Portfolio choice; RM=Attribution; SSN=Account for sample size; TM=Marginal thinking; WAS=Wason task.

Figure 15: Stated confidence (Part 2 decision) by optimality of the response to a cognitive task (Part 1 decision). Based on $N = 5,010$ Part 2 decisions in the *Confidence* condition, pooled across 15 different cognitive tasks. The sample of Part 2 decisions is split by whether the corresponding Part 1 decision was optimal and empirical distribution functions are displayed.

Figure 16: Correlation between optimality of responses to a cognitive task (Part 1 decisions) and institutional choices (Part 2 decisions) by task. Based on $N = 323$ participants in the Auction condition, $N = 387$ in Betting and $N = 337$ in Committee. Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; EQ=Predict others' play; GF: Predict sequence of draws; IR=Backwards induction; KS=Knapsack; PC=Portfolio choice; RM=Attribution; SSN=Account for sample size; TM=Marginal thinking; WAS=Wason task.

Figure 17: Comparison of empirically observed range of confidence-optimality correlations across tasks with numerical simulations. Red line corresponds to empirical data. The simulations are done as follows. In treatment *Confidence*, we take as given the empirical marginal distributions of both confidence and optimality in each task. We then randomly scramble these two variables such that, in expectation, in each task, the confidence-optimality correlation is identical and equal to zero. In any given simulation the actual confidence-optimality correlation in any given task will usually not be zero (due to the finite sample of 334 subjects). We implement this procedure 10,000 times and, for each iteration, save the range (max minus min) of the within-task confidence-optimality correlation. The figure plots the resulting distribution of simulated ranges along with the empirically observed range.

Figure 18: Comparison of empirically observed standard deviation of confidence-optimality correlations across tasks with numerical simulations. Red line corresponds to empirical data. The simulations are done as follows. In treatment *Confidence*, we take as given the empirical marginal distributions of both confidence and optimality in each task. We then randomly scramble these two variables such that, in expectation, in each task, the confidence-optimality correlation is identical and equal to zero. In any given simulation the actual confidence-optimality correlation in any given task will usually not be zero (due to the finite sample of 334 subjects). We implement this procedure 10,000 times and, for each iteration, save the standard deviation of the within-task confidence-optimality correlation. The figure plots the resulting distribution of simulated standard deviations along with the empirically observed standard deviation.

Figure 19: Average confidence and average institutional behavior. For each task, we compute average confidence stated in treatment *Confidence* and plot this against the average Part 2 decision taken in each of the three between-subjects institutional treatments.

Figure 20: Confidence-optimality correlation and institutional improvement for the separate institutions in the between-subjects treatments. The horizontal axis shows the within-task correlation between confidence and optimality in a given task in treatment *Confidence*. The vertical axis shows the performance improvement that is implied by an institution for the respective cognitive task in treatments *Betting*, *Auction* and *Committee*. Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; EQ=Predict others' play; GF: Predict sequence of draws; IR=Backwards induction; KS=Knapsack; PC=Portfolio choice; RM=Attribution; SSN=Account for sample size; TM=Marginal thinking; WAS=Wason task.

Figure 21: Confidence-optimality correlation and institutional improvement using the efficiency measure. The left panel shows the results for the between-subjects treatments and the right panel those for the within-subjects treatments. In the left panel, the horizontal axis shows the within-task correlation between confidence and optimality in a given task in treatment *Confidence*. The vertical axis shows the efficiency of an institution for the respective cognitive task. Efficiency is computed as the aggregate performance rate after institutional filtering minus the the fraction of optimal responses in a cognitive task, all divided by the difference between the maximum possible improvement (given Part 1 responses and the structure of the institution) and the fraction of optimal Part 1 responses. The data are from treatments *Betting*, *Auction* and *Committee*. In the right panel, we show analogous quantities, except that they are all derived from treatments *Betting Within*, *Auction Within* and *Committee Within*. Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; EQ=Predict others' play; GF: Predict sequence of draws; IR=Backwards induction; KS=Knapsack; PC=Portfolio choice; RM=Attribution; SSN=Account for sample size; TM=Marginal thinking; WAS=Wason task.

Figure 22: The peakedness of the distribution of suboptimal answers and the confidence-performance correlation in the between-subjects treatments. The horizontal axis displays the fraction of subjects playing the modal suboptimal answer in a cognitive task (conditional on being wrong). The vertical axis displays the confidence-optimality correlation in treatment *Confidence*. Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; IR=Backwards induction; KS=Knapsack; WAS=Wason task.

Figure 23: Fraction of optimal responses in a cognitive task (Part 1 decision) and average confidence in treatment *Confidence*, separately for each task. Based on $N = 334$ respondents. Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; EQ=Predict others' play; GF: Predict sequence of draws; IR=Backwards induction; KS=Knapsack; PC=Portfolio choice; RM=Attribution; SSN=Account for sample size; TM=Minimize taxation; WAS=Wason task.

Figure 24: Overconfidence and institutional improvement. The left panel shows the results for the between-subjects treatments and the right panel those for the within-subjects treatments. In the left panel, the horizontal axis shows the average level of overconfidence in treatment *Confidence*. The vertical axis shows the average institutional improvement across treatments *Betting*, *Auction* and *Committee*. In the right panel, we show analogous quantities, except that they are all derived from treatments *Betting Within*, *Auction Within* and *Committee Within*. Percentage point improvement is computed as the aggregate performance of the institutional summary statistic minus the raw fraction of optimal responses in a cognitive task, averaged across institutions. The institutional summary statistics are given by the parimutuel market price in *Betting*, the average rate of bias among the set of winners in the *Auction* and the vote share for the optimal decision in *Committee*. The aggregate performance is based on 10,000 randomly constructed ten-subject cohorts for each institution, taking the mean over all samples. Overconfidence is computed as average confidence minus the optimality rate in a task. Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; EQ=Predict others' play; GF: Predict sequence of draws; IR=Backwards induction; KS=Knapsack; PC=Portfolio choice; RM=Attribution; SSN=Account for sample size; TM=Marginal thinking; WAS=Wason task.

C.3 Additional Figures for Within-Subjects Treatments

Figure 25: Fraction of optimal responses in a cognitive task (Part 1 decisions) across tasks in treatments *Betting Within*, *Auction Within* and *Committee Within*. The tasks and optimal responses are described in Appendices A and F. Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; EQ=Predict others' play; GF: Predict sequence of draws; IR=Backwards induction; KS=Knapsack; PC=Portfolio choice; RM=Attribution; SSN=Account for sample size; TM=Thinking at the margin; WAS=Wason task. Error bars are the standard error of the binomial mean.

Figure 26: Institutional choices (Part 2 decisions) by optimality of the response to the cognitive task (Part 1 decision). Based on $N = 1575$ Part 2 decisions in the *Auction Within* condition, $N = 1575$ in *Betting Within* and $N = 1560$ in *Committee Within*, pooled across 15 different cognitive tasks. For each institution, the sample of Part 2 decisions is split by whether the corresponding Part 1 decision was optimal and empirical distribution functions are displayed.

Figure 27: Performance improvement through institutions across tasks in treatments *Betting Within*, *Auction Within* and *Committee Within*. Percentage point improvement is computed as the aggregate performance rate after institutional filtering minus the fraction of optimal responses in a cognitive task. The aggregate performance rate is based on 10,000 randomly constructed 10-subject cohorts for each institution, taking the mean over all samples. Each participant completed all 15 tasks in random order. Based on $N = 105$ participants in the Auction condition, $N = 105$ in Betting and $N = 104$ in Committee. One-standard error bars are conservatively calculated as the ratio of the standard deviations of improvements over these random cohorts divided by the square root of the number of cohorts available in the dataset (e.g., $105/10=10.5$ in Betting). Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; EQ=Predict others' play; GF: Predict sequence of draws; IR=Backwards induction; KS=Knapsack; PC=Portfolio choice; RM=Attribution; SSN=Account for sample size; TM=Marginal thinking; WAS=Wason task.

Figure 28: Within-task correlation between confidence and Part 1 optimality across tasks in treatments *Betting Within*, *Auction Within* and *Committee Within*. Displayed are Pearson correlation coefficients, based on $N = 313$ participants. Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; EQ=Predict others' play; GF: Predict sequence of draws; IR=Backwards induction; KS=Knapsack; PC=Portfolio choice; RM=Attribution; SSN=Account for sample size; TM=Marginal thinking; WAS=Wason task.

Figure 29: Binned scatterplots of institutional decisions against stated confidence in the within-subjects treatments, separately for each institution. Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; EQ=Predict others' play; GF: Predict sequence of draws; IR=Backwards induction; KS=Knapsack; PC=Portfolio choice; RM=Attribution; SSN=Account for sample size; TM=Marginal thinking; WAS=Wason task.

Figure 30: Confidence-optimality correlation and institutional improvement in the within-subjects treatments. The horizontal axis shows the within-task correlation between confidence and optimality in a given task. The vertical axis shows the performance improvement that is implied by an institution for the respective cognitive task. The data are from treatments *Betting Within*, *Auction Within* and *Committee Within*. Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; EQ=Predict others' play; GF: Predict sequence of draws; IR=Backwards induction; KS=Knapsack; PC=Portfolio choice; RM=Attribution; SSN=Account for sample size; TM=Marginal thinking; WAS=Wason task.

Figure 31: Fraction of optimal Part 1 responses and average confidence in treatments *Betting Within*, *Auction Within* and *Committee Within*, separately for each task. Task codes: AC=Acquiring-a-company; BRN=Base rate neglect; BU=Balls-and-urns belief updating; CN=Correlation neglect; CRT=Cognitive reflection test; EGB=Exponential growth calc.; EQ=Predict others' play; GF: Predict sequence of draws; IR=Backwards induction; KS=Knapsack; PC=Portfolio choice; RM=Attribution; SSN=Account for sample size; TM=Minimize taxation; WAS=Wason task.

D Additional Tables

Table 3: Overview of empirical studies eliciting relative calibration

Study	Tasks in main study	Confidence measurement	Measure of aggregation	Main finding	Sample size (main study)	Incentivizes for accuracy
Silver et al. (2021)	Numerical estimates of country populations and historical dates	7-point scale	Revised estimates after discussion in groups of 3-6	Quality of revised decisions higher among groups with better initial confidence calibration	Laboratory 676	Yes
Bennett et al. (2018)	Binary choice general-knowledge questions on topics such as world facts and world history	7-point scale judgment of difficulty	In one condition, respondents could self-select which questions to answer	Crowds consisting of participants who could self-selected questions outperformed crowds consisting of participants who were randomly assigned to questions	Online 144	No
Minson et al. (2018)	Numerical estimates of CEO salaries, weights of animals and U.S. demographic statistics	5-point scale	Joint estimates after discussion with one other subject	Individual confidence unrelated to performance. Discussion outperforms average individual decisions in questions where subjects tend to make very large errors.	Laboratory 180	No
Cain et al. (2015)	Multiple choice trivia quiz questions	Stated belief distribution of obtaining different cumulative scores	Selection into competition for high prize based on hard quiz versus for low prize based on easy quiz.	Selection into competition strongly predicted by overplacement relative to others. Overplacement more likely for easy quiz.	Laboratory 160	Yes
Koriat (2012)	Binary choice in perceptual and general knowledge	Likelihood of being correct (50-100%)	No further choice. Virtual dyads are formed randomly and the response with higher confidence is selected as the group outcome.	Dyads outperform average individual judgments on questions where average accuracy high, which tend to be questions where accuracy and confidence are positively correlated.	Laboratory 40	No
Snizek and Van Swol (2001)	Multiple choice questions on knowledge about computers	Likelihood of being correct (0-100%)	Advisor recommends an answer to a Judge.	Confidence and accuracy positively correlated on average. Higher Advisor confidence predicts stronger effects of recommendations on Judges.	Laboratory 152	Yes

Notes. This table summarizes a selection of previous experimental work reporting data that permit the calculation of confidence calibration. Specifically, this includes studies that measure objective task performance alongside with respondents' confidence in their performance.

Table 4: Determinants and correlates of subject-level overconfidence

	Overconfidence
Optimality Rate	−84.933*** (7.111)
Age	0.025 (0.065)
Male	8.928*** (1.837)
College?	4.036** (1.923)
Income	0.00001 (0.00002)
Black	3.831 (4.147)
Hispanic	−14.553*** (5.197)
Other Race	−1.489 (5.860)
White	−1.099 (3.285)
Constant	55.441*** (4.315)
Observations	334
R ²	0.362
Adjusted R ²	0.344
Residual Std. Error	16.076 (df = 324)
F Statistic	20.413*** (df = 9; 324)

Notes. OLS estimates of overconfidence on demographic variables. The unit of the observation is an individual subject and the dependent variable is the difference between the subject's average confidence and optimality rate in treatment *Confidence*. Independent variables include age in years, an indicator for being male, an indicator for having graduated from college, income and four indicator variables for race (Asian is the excluded variable). * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

E Disclosure Statement

The paper reports analyses for all experimental conditions and measures that were collected. All data exclusions are reported. Sample sizes were determined based on a pilot study.

F Experimental Instructions

F.1 Treatment *Confidence*

Instruction screens

Instructions (1/2)

Please read these instructions carefully. There will be comprehension checks. If you fail those, you will not be able to participate in the study and earn a bonus.

This study consists of a total of 15 tasks. Each of these tasks consists of two parts:

Part 1: You will make a decision by answering a question. Your decision potentially determines your bonus payment. In each question, there is going to be an optimal decision, by which we mean a decision that maximizes your earnings, on average.

Part 2: We will ask you how certain you are that your decision in Part 1 was optimal. Your response to this question does not affect your bonus.

Your bonus

As noted above, there are a total of 15 tasks in this study. In each task, you will make one earnings-relevant decision (Part 1). At the end of the study, the computer will randomly select one of your 15 decisions to determine your bonus. Because we only pay you based on a single decision of yours, there is no point for you in strategizing across decisions or tasks. You should simply always take the decision that you think is best.

Instructions (2/2)

Part 1: Your decision

As we described on the previous screen, in each task you will first make a decision (Part 1).

For example, in Part 1 we might ask you a question like "How many cities with more than 2 million people are there in the United States? You will receive 100 points if your decision is correct." Your Part 1 decision is simply your answer to this question, and your decision is "optimal" if it is correct.

Part 2: Your certainty

In Part 2, we ask you "How certain are you that your decision was optimal?" When we ask this question, we are interested in your assessment of how likely it is (in %) that your decision was optimal. You use a slider like the one below to give your answer. If you are completely sure your answer was correct, you should set the slider all the way to the right (100%). If you are certain your answer was not correct, you should set it all the way to the left (0%). In general, the more likely you think it is that you answered the Part 1 question correctly, the further to the right you should set your Part 2 slider.

You need to click on the slider to see the handle.

EXAMPLE:

Example of a task

Here is an example of how a task proceeds. Once the study begins, you will see these two parts on consecutive screens. We just summarize them on one screen here to give you an overview of how things work.

Part 1: Your decision

How many cities with more than 2 million people are there in the United States? You will receive 100 points if your decision is correct.

Part 2: Your certainty

Your decision is considered "optimal" if it is correct.

I am **PLEASE CLICK SLIDER** certain that my decision in Part 1 was optimal.

Once you click the next button, you will not be able to go back to the instructions and the comprehension check questions will start.

Comprehension questions

Comprehension check

To verify your understanding of the instructions, please answer the comprehension questions below. If you get one or more of them wrong, you will not be allowed to participate in the study and you will not be able to earn a bonus. In each question, exactly one response option is correct.

1. How is your bonus determined?

I will make 15 decisions in total, and every one of them will get paid. Thus, I can strategize across decisions to hedge my bets.

I will make 15 decisions in total. The computer will randomly select one of them, and my bonus will depend on my answer to this one question. Thus, there is no point for me in strategizing across decisions.

2. Which of the statements about Part 2 is correct?

There is no relationship between Part 1 and Part 2.

My decision in Part 2 builds on my decision in Part 1. Once I get to Part 2, I cannot change my Part 1 decision.

My decision in Part 2 builds on my decision in Part 1. Once I get to Part 2, I can go back to Part 1 and change my Part 1 decision.

3. Suppose that you DID take the optimal decision in Part 1 of a task. Which Part 2 decision would then be more reflective of your actual performance?

If I stated that I'm 70% certain I got the task right

If I stated that I'm 20% certain I got the task right

4. Suppose that you DID **NOT** take the optimal decision in Part 1 of a task. Which Part 2 decision would then be more reflective of your actual performance?

If I stated that I'm 70% certain I got the task right

If I stated that I'm 20% certain I got the task right

Example screen

Part 2: Your certainty

Task 1/15

You can review your decision from Part 1 by clicking on the back arrow below. You can review the instructions for Part 2 [here](#). Your decision is considered "optimal" if it maximizes your total earnings.

How certain are you that your decision in Part 1 was optimal?

Not at all certain

0%10%20%30%40%50%60%70%80%90%100%

Fully certain

I am PLEASE CLICK SLIDER certain that my decision in Part 1 was optimal.

F.2 Treatment *Betting*

Instructions (1/2)

Please read these instructions carefully. There will be comprehension checks. If you fail those, you will not be able to participate in the study and earn a bonus.

This study consists of a total of 15 tasks. Each of these tasks consists of two parts:

Part 1: You will make a decision by answering a question. Your decision potentially determines your bonus payment. In each question, there is going to be an optimal decision, by which we mean a decision that maximizes your earnings, on average.

Part 2: You will make another decision that relates to the decision you made in Part 1. This decision will also potentially determine your bonus.

Your bonus

As noted above, there are a total of 15 tasks in this study. In each task, you will make two earnings-relevant decisions (Part 1 and Part 2), for a total of 30 decisions. At the end of the study, the computer will randomly select one of your 30 decisions to determine your bonus. Because we only pay you based on a single decision of yours, there is no point for you in strategizing across decisions or tasks. You should simply always take the decision that you think is best.

Instructions (2/2)

Part 1: Your decision

As we described on the previous screen, in each task you will first make a decision (Part 1).

For example, in Part 1 we might ask you a question like "How many cities with more than 2 million people are there in the United States? You will receive 100 points if your decision is correct." Your Part 1 decision is simply your answer to this question, and your decision is "optimal" if it is correct.

Part 2: Bet based on your decision

Once you get to Part 2, you cannot change your Part 1 decision. However, your decision in Part 2 builds on your decision in Part 1. This will work as follows:

- All participants in this study will make a decision in Part 1 by answering the exact same question as you did. In Part 2, 10 participants (including yourself) take part in a betting market that relates to their decision from Part 1.
- Each participant is given a budget of 100 points to participate in the betting market. You can use the slider below to decide **how many points to bet that your decision in Part 1 was optimal. Every point that you don't bet you get to keep.**
- Each of the other 9 participants will also decide how many of their 100 points to bet on the optimality of their decision.
- Based on how much everyone bets, and whether their decisions from Part 1 were actually optimal or not, we determine your bonus as follows:
 - **If your decision in Part 1 was not optimal, every point you bet will be lost.**
 - **If your decision in Part 1 was optimal, every point you bet will yield a positive profit for you.** In this case, your bonus is given by:

$$\text{Bonus} = \text{Number of points you bet} * (\text{Number of points bet by all participants}) / (\text{Number of points bet by participants whose Part 1 decision was optimal})$$

- While this may sound complicated, what it means is relatively simple: **if your decision in Part 1 was optimal, you're guaranteed to earn back at least what you bet, and probably more.**

You need to click on the slider to see the handle.

EXAMPLE:

I want to bet **PLEASE CLICK SLIDER** point(s) that my own decision in Part 1 was optimal.

Example of a task

Here is an example of how a task proceeds. Once the study begins, you will see these two parts on consecutive screens. We just summarize them on one screen here to give you an overview of how things work.

Part 1: Your decision

How many cities with more than 2 million people are there in the United States? You will receive 100 points if your decision is correct.

Part 2: Bet based on your decision

I want to bet **PLEASE CLICK SLIDER** point(s) that my own Part 1 decision was optimal.

Once you click the next button, you will not be able to go back to the instructions and the comprehension check questions will start.

Comprehension questions

Comprehension check

To verify your understanding of the instructions, please answer the comprehension questions below. If you get one or more of them wrong, you will not be allowed to participate in the study and you will not be able to earn a bonus. In each question, exactly one response option is correct.

1. How is your bonus determined?

I will make 30 decisions in total, and every one of them will get paid. Thus, I can strategize across decisions to hedge my bets.

I will make 30 decisions in total. The computer will randomly select one of them, and my bonus will depend on my answer to this one question. Thus, there is no point for me in strategizing across decisions.

2. Which of the statements about Part 2 is correct?

There is no relationship between Part 1 and Part 2.

My decision in Part 2 builds on my decision in Part 1. Once I get to Part 2, I cannot change my Part 1 decision.

My decision in Part 2 builds on my decision in Part 1. Once I get to Part 2, I can go back to Part 1 and change my Part 1 decision.

3. Suppose that you DID take the optimal decision in Part 1 of a task. Which Part 2 decision would then lead to higher Part 2 earnings for you?

If I bet 70 points

If I bet 20 points

4. Suppose that you DID **NOT** take the optimal decision in Part 1 of a task. Which Part 2 decision would then lead to higher Part 2 earnings for you?

If I bet 70 points

If I bet 20 points

Example screen

Part 2: Bet based on your decision

Task 1/15

You can review your decision from Part 1 by clicking on the back arrow below. You can review the instructions for Part 2 [here](#).

How many points do you want to bet that your decision in Part 1 was optimal?

I want to bet **PLEASE CLICK SLIDER** point(s) that my own decision in Part 1 was optimal.

F.3 Treatment Auction

Instructions (1/2)

Please read these instructions carefully. There will be comprehension checks. If you fail those, you will not be able to participate in the study and earn a bonus.

This study consists of a total of 15 tasks. Each of these tasks consists of two parts:

Part 1: You will make a decision by answering a question. Your decision potentially determines your bonus payment. In each question, there is going to be an optimal decision, by which we mean a decision that maximizes your earnings, on average.

Part 2: You will make another decision that relates to the decision you made in Part 1. This decision will also potentially determine your bonus.

Your bonus

As noted above, there are a total of 15 tasks in this study. In each task, you will make two earnings-relevant decisions (Part 1 and Part 2), for a total of 30 decisions. At the end of the study, the computer will randomly select one of your 30 decisions to determine your bonus. Because we only pay you based on a single decision of yours, there is no point for you in strategizing across decisions or tasks. You should simply always take the decision that you think is best.

Instructions (2/2)

Part 1: Your decision

As we described on the previous screen, in each task you will first make a decision (Part 1).

For example, in Part 1 we might ask you a question like "How many cities with more than 2 million people are there in the United States? You will receive 100 points if your decision is correct." Your Part 1 decision is simply your answer to this question, and your decision is "optimal" if it is correct.

Part 2: Bid for a potential bonus based on your decision

Once you get to Part 2, you cannot change your Part 1 decision. However, your decision in Part 2 builds on your decision in Part 1. This will work as follows:

- All participants in this study will make a decision in Part 1 by answering the exact same question as you did. In Part 2, 10 participants (including yourself) will take part in an **auction** that relates to your decisions in Part 1.
- The winners of this auction will be eligible for an additional bonus. However, as explained below, the winners of the auction only receives a bonus from winning the auction if they **also** made the optimal decision in Part 1.
- You and the other participants are each given a budget of 100 points to participate in the auction. You can use the slider below to decide **how many points (maximum 100) to bid. Every point that you don't bid you get to keep no matter what.**
- The other participants will also decide how many of their 100 points to bid to get the potential bonus.
- Your Part 2 bonus is then determined according to the outcome of the auction:
 - The five highest bids win the auction. That is, the auction will have FIVE winners. If multiple participants make exactly the same fifth-highest bid, the winner will be chosen randomly from among those bidders.
 - If you are NOT among the five highest bidders, you simply keep your entire initial budget of 100 points, and you won't have to pay the bid you make.
 - If you ARE among the five highest bidders, you will have to pay the amount you bid out of your 100-point budget. In addition, you will receive a bonus:
 - If your Part 1 decision was optimal, your bonus from being a winner in the auction is 100 points.
 - If your Part 1 decision was not optimal, your bonus from being a winner in the auction is 0 points.
- **While this may sound complicated, what it means is relatively simple: if your decision in Part 1 was optimal, you receive a bonus of 100 points from being one of the winners in the auction in Part 2, but you will also have to pay your winning bid. If, on the other hand, your decision in Part 1 was not optimal, you don't receive a bonus from being one of the winners in the auction, but you will still have to pay your winning bid.**

You need to click on the slider to see the handle.

EXAMPLE:

I want to bid **PLEASE CLICK SLIDER** point(s) to get a bonus that depends on my Part 1 decision.

Example of a task

Here is an example of how a task proceeds. Once the study begins, you will see these two parts on consecutive screens. We just summarize them on one screen here to give you an overview of how things work.

Part 1: Your decision

How many cities with more than 2 million people are there in the United States? You will receive 100 points if your decision is correct.

Part 2: Bid for a potential bonus based on your decision

I want to bid **PLEASE CLICK SLIDER** point(s) to get a bonus that depends on my Part 1 decision.

Once you click the next button, you will not be able to go back to the instructions and the comprehension check questions will start.

Comprehension questions

Comprehension check

To verify your understanding of the instructions, please answer the comprehension questions below. If you get one or more of them wrong, you will not be allowed to participate in the study and you will not be able to earn a bonus. In each question, exactly one response option is correct.

1. How is your bonus determined?

I will make 30 decisions in total, and every one of them will get paid. Thus, I can strategize across decisions to hedge my bets.

I will make 30 decisions in total. The computer will randomly select one of them, and my bonus will depend on my answer to this one question. Thus, there is no point for me in strategizing across decisions.

2. Which of the statements about Part 2 is correct?

There is no relationship between Part 1 and Part 2.

My decision in Part 2 builds on my decision in Part 1. Once I get to Part 2, I cannot change my Part 1 decision.

My decision in Part 2 builds on my decision in Part 1. Once I get to Part 2, I can go back to Part 1 and change my Part 1 decision.

3. Suppose that you DID take the optimal decision in Part 1 of a task. Which Part 2 decision would then lead to higher Part 2 earnings for you, assuming everyone else bids 50?

If I bid 70 points

If I bid 20 points

4. Suppose that you DID **NOT** take the optimal decision in Part 1 of a task. Which Part 2 decision would then lead to higher Part 2 earnings for you, assuming everyone else bids 50?

If I bid 70 points

If I bid 20 points

Example screen

Part 2: Bid for a potential bonus based on your decision

Task 1/15

You can review your decision from Part 1 by clicking on the back arrow below. You can review the instructions for Part 2 [here](#).

How many points do you want to bid for receiving the bonus that depends on your Part 1 decision?

I want to bid **PLEASE CLICK SLIDER** point(s) to get a bonus that depends on my Part 1 decision.

F.4 Treatment Committee

Instructions (1/2)

Please read these instructions carefully. There will be comprehension checks. If you fail those, you will not be able to participate in the study and earn a bonus.

This study consists of a total of 15 tasks. Each of these tasks consists of two parts:

Part 1: You will make a decision by answering a question. Your decision potentially determines your bonus payment. In each question, there is going to be an optimal decision, by which we mean a decision that maximizes your earnings, on average.

Part 2: You will make another decision that relates to the decision you made in Part 1. This decision will also potentially determine your bonus.

Your bonus

As noted above, there are a total of 15 tasks in this study. In each task, you will make two earnings-relevant decisions (Part 1 and Part 2), for a total of 30 decisions. At the end of the study, the computer will randomly select one of your 30 decisions to determine your bonus. Because we only pay you based on a single decision of yours, there is no point for you in strategizing across decisions or tasks. You should simply always take the decision that you think is best.

Instructions (2/2)

Part 1: Your decision

As we described on the previous screen, in each task you will first make a decision (Part 1).

For example, in Part 1 we might ask you a question like "How many cities with more than 2 million people are there in the United States? You will receive 100 points if your decision is correct." Your Part 1 decision is simply your answer to this question, and your decision is "optimal" if it is correct.

Part 2: Vote based on your decision

Once you get to Part 2, you cannot change your Part 1 decision. However, your decision in Part 2 builds on your decision in Part 1. This will work as follows:

- All participants in this study will make a decision in Part 1 by answering the exact same question as you did. In Part 2, we will combine the decisions of 10 participants (including yourself) through a voting procedure to determine the group's Part 2 earnings.
- You can submit **up to 100 votes for your own decision from Part 1**. The more votes you choose to submit, the more your decision will influence the group's earnings.
 - For instance, if you choose to submit 0 votes, you are choosing that your decision from Part 1 does not have any influence on the group's earnings. If you choose to submit 100 votes, you are choosing to have as much influence as possible. You can choose how many votes you'd like to submit using a slider like the one below
- Each of the other 9 participants will also decide how many of their 100 votes to submit for their own decision from Part 1. **The group's earnings are higher the more total votes (across all participants in your group) get submitted for the optimal decision, and lower the more total votes get submitted for decisions that are not optimal.**
- Important: You and all other participants will all earn an identical amount if Part 2 is selected to count for payment, regardless of how many votes you each individually choose to submit.** Everyone's bonus from Part 2 is only determined by the **fraction of total submitted votes** that are for the optimal decision. Therefore, from the perspective of your earnings, it doesn't matter whether you or other people submit votes – **all that matters is that the votes that do get submitted (whoever they are from) are for the optimal decision.** In case you're interested, the specific formula we use to determine everyone's bonus is given by

$$\text{Bonus} = 100 * (\text{Number of votes for the optimal decision}) / (\text{Total number of votes})$$

You need to click on the slider to see the handle.

EXAMPLE:

I want to submit **PLEASE CLICK SLIDER** vote(s) for my own Part 1 decision.

Example of a task

Here is an example of how a task proceeds. Once the study begins, you will see these two parts on consecutive screens. We just summarize them on one screen here to give you an overview of how things work.

Part 1: Your decision

How many cities with more than 2 million people are there in the United States? You will receive 100 points if your decision is correct.

Part 2: Vote based on your decision

I want to submit **PLEASE CLICK SLIDER** vote(s) for my own Part 1 decision.

Once you click the next button, you will not be able to go back to the instructions and the comprehension check questions will start.

Comprehension questions

Comprehension check

To verify your understanding of the instructions, please answer the comprehension questions below. If you get one or more of them wrong, you will not be allowed to participate in the study and you will not be able to earn a bonus. In each question, exactly one response option is correct.

1. How is your bonus determined?

I will make 30 decisions in total, and every one of them will get paid. Thus, I can strategize across decisions to hedge my bets.

I will make 30 decisions in total. The computer will randomly select one of them, and my bonus will depend on my answer to this one question. Thus, there is no point for me in strategizing across decisions.

2. Which of the statements about Part 2 is correct?

There is no relationship between Part 1 and Part 2.

My decision in Part 2 builds on my decision in Part 1. Once I get to Part 2, I cannot change my Part 1 decision.

My decision in Part 2 builds on my decision in Part 1. Once I get to Part 2, I can go back to Part 1 and change my Part 1 decision.

3. Suppose that you DID take the optimal decision in Part 1 of a task. Which Part 2 decision would then lead to higher Part 2 earnings for you, on average?

If I submit 70 votes

If I submit 20 votes

4. Suppose that you DID **NOT** take the optimal decision in Part 1 of a task. Which Part 2 decision would then lead to higher Part 2 earnings for you, on average?

If I submit 70 votes

If I submit 20 votes

Example screen

Part 2: Vote based on your decision

Task 1/15

You can review your decision from Part 1 by clicking on the back arrow below. You can review the instructions for Part 2 [here](#).

How many votes do you want to submit for your own decision from Part 1?

I want to submit **PLEASE CLICK SLIDER** vote(s) for my own decision from Part 1.

F.5 Task Descriptions

Acquiring a company

Part 1: Your decision

Task 1/15

- You have a budget of 180 points. You can either keep it or use it to buy a company.
- Bob is selling his company. The **VALUE** of Bob's company to him is either **20** or **120 points**, but you do not know which. There is a **50% chance** it is worth 20 points to him and a **50% chance** it is worth 120 points to him.
- Bob's company has a higher value to you than to Bob.** If you acquire his company, it will pay you **1.5 times** its value to Bob. Therefore, if the value of the company turns out to be 20 points for Bob, it would be worth 30 points for you. If the value of the company turns out to be 120 points for Bob, it would be worth 180 points for you.
- The realized value is determined randomly by the computer, and you will not know the value until after you've made your decision.
- You can make a **PRICE** offer to Bob of up to 180 points.
- Your earnings will be determined as follows:
 - If you offer a **PRICE that is at least as high** as Bob's realized **VALUE**, Bob will accept your offer, and your earnings will be $Earnings = (Your\ budget) + 1.5 * (Bob's\ VALUE) - (the\ PRICE\ you\ offered)$
 - If you offer a **PRICE less** than Bob's realized **VALUE**, you will not acquire his company and your profits will be $Earnings = Your\ budget$

How much do you bid for Bob's company?

 point(s)

Knapsack

Part 1: Your decision

Task 1/15

- There are 12 **ITEMS** shown in the Table below. Your task is to choose one or more of these items.
- Each item has a **VALUE** in points to you. Your earnings for this task are given by the **SUM OF VALUES** of the items you choose.
- However, each item also has a **WEIGHT**. The total **SUM OF WEIGHTS** of the items you choose **CANNOT EXCEED 14**. If your selection exceeds this weight limit, you will earn nothing.

Which items do you choose? (Please click on the columns)

	#1	#2	#3	#4	#5	#6	#7	#8	#9	#10	#11	#12
Value	2	3	4	5	6	9	8	7	6	5	8	9
Weight	3	4	6	3	5	13	6	9	2	4	7	7

Current sum of weights chosen (cannot exceed 14): 0

Iterated reasoning / backward induction

Part 1: Your decision

Task 1/15

- Your task is to **pick two numbers between 0 and 100 each**. Let's call these numbers A and B.
- You will earn more points the **closer** A and B each are to $\frac{2}{3}$ of the **average** of A and B.
- Specifically, we will pay you 100 base points and subtract from this:
 - The absolute difference between A and $\frac{2}{3}$ of the average of both numbers AND
 - The absolute difference between B and $\frac{2}{3}$ of the average of both numbers.
- You cannot make losses, meaning you always earn at least 0 points.
- The rules are:
 - All numbers between 0 and 100 are acceptable, including 0 and 100.
 - You are welcome to pick the same number for A and B, or different numbers for each.
- **While all this may sound complicated, all it means is that you will receive more points the closer your chosen numbers A and B are to $\frac{2}{3}$ of the average of the two numbers.**

Which numbers do you choose?

A

B

Exponential growth bias

Part 1: Your decision

Task 1/15

- Suppose a stock starts at a value of \$100.
- It grows by 5% each year relative to its **beginning-of-year value**.
- **How much is it worth after 20 years?** If necessary, round your decision to the nearest dollar value.
- We will pay you more points the closer your decision is to the correct answer.
 - Specifically, we will pay you 100 base points and subtract from this the absolute difference between your decision and the correct stock value. For example, if the absolute difference between the true stock value and your decision is \$10, we will subtract 10 points.
 - You cannot make losses, meaning you always earn at least 0 points.

How much is the stock worth after 20 years? (round to the nearest integer)

\$

Correlation neglect

Part 1: Your decision

Task 1/15

- There are three people: Ann, Bob and Charlie. Each of them is interested in estimating the weight of a water bucket in pounds.
- Ann and Bob both **get to take a peek at the bucket**. They are equally good at estimating weight. Each of them gets weight estimates right, on average, but sometimes makes **random mistakes**. Ann and Bob are equally likely to make mistakes in any given estimate they make.
- Ann and Bob both share their estimates with Charlie, who has never seen the bucket. Because he has never seen the bucket, Charlie computes his best estimate of the weight of the bucket as the average of the estimates of Ann and Bob.
- **You have never seen the bucket either, but you're asked to produce an estimate of its weight.** You now talk to Ann and Charlie. They share the following estimates with you:
 - Ann's estimate: 70
 - Charlie's estimate: 40
- **Your task is to estimate the weight of the bucket.**
- We will pay you more points the closer your decision is to the statistically-correct estimate given the information you are provided.
 - Specifically, we will pay you 100 points if your decision corresponds to this correct answer. We subtract 3 points for every number you are away from the correct answer.
 - You cannot make losses, meaning you always earn at least 0 points.

What is your best estimate of the weight of the bucket? (round to the nearest integer)

CRT

Part 1: Your decision

Task 1/15

It takes 6 machines 6 days to produce 6 cars. **How long would it take 12 machines to produce 12 cars?** (round to the nearest integer)

 day(s)

We will pay you 100 points if you get it right, and nothing otherwise.

Wason

Part 1: Your decision

Task 1/15

- Suppose your friend has a special deck of cards.
- His special deck of cards all have **numbers** (odd or even) on one side and **colors** (brown or green) on the other side. Suppose that the 4 cards below are from his deck.
- Your friend claims that: "In my deck of cards, all of the cards with an even number on one side are green on the other."

We will pay you 100 points if:

- you turn over **ALL** of the card(s) that can be helpful in determining whether your friend's statement is true AND
- you do not turn over **ANY** of the cards that **CANNOT** be helpful in assessing whether his statement is true.

In other words, you won't earn 100 points if you turned over a card that isn't actually helpful in determining whether your friend's statement is true. Likewise, you won't earn 100 points if you failed to turn over a card that is actually helpful.

Which card(s) do you want to turn over?

Thinking at margin

Part 1: Your decision

Task 1/15

- You are given 100 points (money) to store in two different **BANK ACCOUNTS**, A and B. Points stored in each account are **TAXED** by the government in different ways. You can store your points in 20-unit increments.
- Here is how much you pay in taxes for account A based on the total amount stored:

Investment in account A (in points)	20 total points stored	40 total points stored	60 total points stored
Total taxes to be paid for account A (in points)	4	12	24

- For instance, if you store 20 points in account A, you pay 4 points, leaving you with 16 points in account A after taxes. If you store 40 points, you pay 12 points in taxes, leaving you with 28 points in account A after taxes, etc.
- Here is how much you pay in taxes for account B based on the total amount stored:

Investment in account B (in points)	20 total points stored	40 total points stored	60 total points stored
Total taxes to be paid for account B (in points)	10	20	30

- For instance, if you store 20 points in account B, you pay 10 points in taxes, leaving you with 10 points in account B after taxes. If you store 40 points, you pay 20 points in taxes, leaving you with 20 points in account B after taxes, etc.
- In total, you can put 100 points into the bank.
 - We already put 40 points into bank account A for you.
 - We also put another 40 points into account B for you.
 - You now have an **ADDITIONAL 20** points to put into the bank. You must now decide into which account you would like to put these last 20 points.
- We will pay you the 100 points in the bank, minus total taxes from accounts A and B.

Into which account do you put your additional 20 points?

Account A

Account B

We noticed a typo in the instructions of this task after beginning the data collection: In the first sentence, instead of “100 points”, the instructions read “60 points”. Despite this typo, we believe that it was still possible to follow the task description and arrive at the correct decision. The optimization rate in this task did not change after fixing this typo: it was 28.28% (N=1,372) before and 28.24% (N=170) after correcting the mistake. In all our analysis, we thus pool these data.

Portfolio choice and 1/N

Part 1: Your decision

Task 1/15

- In this task, you'll be asked to choose an investment portfolio that consists of different stocks.
- There are **four stocks** that pay you different amounts of money depending on the color of a ball that a computer will randomly draw. Each of the colors **red**, **blue**, and **green** is equally likely to get selected by the computer.
- The table below shows you the **payment rate** of each stock, depending on which ball the computer randomly draws. For example, a realized return of 10% means that if you invest 20 points, you end up with 22 points. Likewise, a realized return of -10% means that if you invest 20 points, you end up with 18 points.

Color of ball drawn	Return of Stock A	Return of Stock B	Return of Stock C	Return of Stock D
Red	13%	-2%	-9%	17%
Blue	-8%	8%	12%	-9%
Green	8%	6%	7%	7%

- In total, you need to invest **100 points** across these stocks. You can select one of the portfolios (combinations of stock purchases) below.
- The computer will randomly draw a ball and pay you the total amount earned across the stocks in your portfolio.

Portfolio	Points in Stock A	Points in Stock B	Points in Stock C	Points in Stock D
I	50	25	0	25
II	25	25	25	25

Which investment portfolio do you choose?

Portfolio I

Portfolio II

Balls and urns

Part 1: Your decision

Task 1/15

- There are **two bags**. One bag contains **70 red chips** and **30 blue chips**. The other one contains **30 red chips** and **70 blue chips**.
- We secretly flipped a (fair) coin. If it came up **HEADS**, we chose the bag with **more red chips**. If the coin came up **TAILS**, we chose the bag with **more blue chips**. **You do not observe which bag was selected.**
- Next, **we drew one chip at random from the bag selected by the coin toss**. You will learn the color of this randomly-drawn chip below. Then, you need to guess (in percent) which bag was selected.
- We will pay you more points the closer your decision is to the statistically-correct percentage chance given the information you are provided.
 - Specifically, we will pay you 100 points if your decision corresponds to this correct answer. We subtract 3 points for every percentage point you are away from the correct answer.
 - You cannot make losses, meaning you always earn at least 0 points.

You are told that **one red chip** has randomly been drawn from the secretly selected bag. What do you think is the likelihood (percentage chance) that the selected bag is the one with **more red chips**? (round to the nearest integer)

%

Sample size neglect

Part 1: Your decision

Task 1/15

- There are **two factories** that make office chairs. The **larger** factory produces **45 chairs** each day, and the smaller factory produces **15 chairs** each day.
- For both factories, there is a **10% random chance** that any given chair is **defective**. However, since this is random, the exact percentage varies from day to day. Sometimes it may be higher than 10%, sometimes lower.
- For a period of 1 year, each factory recorded the days on which **MORE THAN 20%** of the chairs were defective.

Which factory do you think recorded more days on which more than 20% of the chairs were defective?

The larger factory

The smaller factory

About the same (that is, within 2% of each other)

We will pay you 100 points if your decision corresponds to the statistically-correct option given the information you are provided, and nothing otherwise.

Base rate neglect

Part 1: Your decision

Task 1/15

- Assume that, on average, out of every 100 bicycles produced by a bike manufacturer, **90 are good** and **10 are defective**.
- There is a quality control machine that classifies bicycles as either good or defective at the end of the production process. This quality control machine makes classification mistakes from time to time. On average, the machine **correctly** classifies a bicycle (as good or defective) **75 out of 100 times**, but **incorrectly** classifies it **25 out of 100 times**.
- Now a bicycle produced by the manufacturer has randomly been selected. Next, this specific bicycle was run through the quality control machine, and you will learn about the machine's classification below. Based on this classification, your task is to state the likelihood (percentage chance) that this specific bicycle is actually defective.
- We will pay you more points the closer your decision is to the statistically-correct percentage chance given the information you are provided.
 - Specifically, we will pay you 100 points if your decision corresponds to this correct answer. We subtract 3 points for every percentage point you are away from the correct answer.
 - You cannot make losses, meaning you always earn at least 0 points.

You learn that the randomly selected bicycle has been **classified as defective** by the quality control machine. **What do you think is the likelihood (percentage chance) that it is actually defective?** (round to the nearest integer)

%

Gambler's fallacy

Part 1: Your decision

Task 1/15

Imagine you are tossing a **fair coin**. After eight tosses you observe the following result (where **T** stands for **TAILS** and **H** stands for **HEADS**):

T - T - T - H - T - H - H - H

Which event is more likely to happen on the next coin toss?

Heads is more likely

Tails is more likely

Both are equally likely

We will pay you 100 points if your decision corresponds to the statistically-correct option given the information you are provided, and nothing otherwise.

Regression to the mean / misattribution

Part 1: Your decision

Task 1/15

- The **average** score on a standard **IQ test** is **100**. Suppose a **randomly** selected individual has obtained a score of **140**.
- Suppose further that an IQ score is the sum of both **true ability** and **random good or bad luck**. The luck component can be positive or negative but equals zero on average (over all people).

Which of the following statements is correct?

This person's true IQ is more likely to be above than below 140.

This person's true IQ is more likely to be below than above 140.

This person's true IQ is equally likely to be above or below 140.

We will pay you 100 points if your decision corresponds to the statistically-correct statement given the information you are provided, and nothing otherwise.
